Case Report

New-born born with patent vitellointestinal duct with prolapsed (intussusceptions) of proximal and distal ileal loop: A case presentation

Fariha Akil Fazal*, James Muturi Ndungu, Humdun Said, Josephat Njiru, Fred Kambuni

1. Background

During the fifth week of gestation, midgut enlarges rapidly and as it becomes too large for the abdominal cavity, it herniates through the umbilical cord. The apex of the herniated midgut is continuous with VID and yolk sac. Superior mesenteric artery forms the axis of this herniated midgut. Around tenth week of gestation herniated midgut returns back into the peritoneal cavity [1,2]. During this complex developmental process several anomalies may occur because of the complexity of the process. Examples include bowel atresias and stenoses, abnormalities of the vitellointestinal duct (Meckel's diverticulum, patent vitellointestinal duct (PVID), umbilical fistulas, umbilical sinus tracts, umbilical cysts and umbilical polyps), failure of ceacal descent, malrotation, malfixation, reversed bowel rotation and exomphalos [1–3].

2. Case presentation

An 18 h old male new-born was referred to Kenyatta National Hospital with a mass protruding from the umbilicus since birth. Baby was born at full term via simple vaginal delivery to a parous 3 mother. The mother as well as the referral letter confirmed that the baby was born with the mass. Antenatal scans were reported to be normal and there was no history of polyhydramnios. Birth weight was 2500 g and Apgar scores were 9/1, 10/1, 10/10.

On examination at 18 h, new-born was comfortable and alert. Abdominal examination revealed a bright red 'Y' shaped loop of small intestine was protruding from the umbilical ring. It was fixed to the umbilicus, with easily bleeding mucosa and irreducibility. Rest of the abdomen was not distended nor tender (Figs. 1 and 2). Bowel sounds were absent. There was no bilious aspirate in the orogastric tube. Anal opening was normally placed and patent, however, he had not passed any meconium. Patient had passed clear urine twice and the bladder was not palpable. Rest of the systemic examination was normal.

Laboratory investigation including full hemogram, biochemistry and coagulation profile were normal. A plain abdominal radiograph in supine and lateral decubitus position showed normal bowel pattern with no air fluid levels and air in the pelvis (Fig. 3). The neo born was started on intravenous fluids, antibiotics intravenous ceftriaxone (100 mg/kg/day) and metronidazole (30 mg/kg/day) and intramuscular vitamin K 5 mg.

Patient was prepared for an emergency laparotomy because of the prolapsed ileal loops. Examination under anaesthesia revealed that prolapsed bowel loops were intussuscepted proximal and distal ileal segment through patent VID. There was no mass palpable underneath to suggest any enteral or urachal cyst.

We made a transumbilical circumferential incision in to the...
peritoneum. The outer surface of the prolapsed loop was firmly adherent to all the layers of the anterior abdominal wall and therefore had to be meticulously dissected of the anterior abdominal wall. Continuity with proximal and distal bowel loop as well as the relationship with the umbilical ring and appendix was confirmed. Then both proximal and distal loops were gently reduced with ease. There was no bowel wall edema and the mucosa was health. After complete reduction defect connecting the small bowel with umbilicus was found to be approximately 2 cm wide. It was resected and anastomosed after ligating the aberrant blood supply to the Meckel’s diverticulum (Fig. 4). Umbilicus was closed with a purse string suture (Fig. 5).

Patient passed meconium on first operative day after which the orogastric tube was removed. He was started on breast milk on the second day. Subsequently the patient was discharged on the forth Post-operative day and has been doing well for over six months of follow up.

3. Discussion

Vitellointestinal duct (VID) or Omphalomesenteric duct connecting the primitive gut to the yolk sac usually obliterates around the seventh or eighth week of gestation. Failure to obliterate may lead to variety of congenital anomalies including; Meckel’s diverticulum, vitelline cord, umbilical sinus, enteric fistula and or hemorrhagic umbilical mass [1–4].

Double intussusception of the small bowel through a patent VID is very rare entity. To date only 14 cases have been reported in the English medical literature. These include: Elebute and Ransome-Kuti in 1965 [5], Davis and Kehm in 1967 [6], Lai and Dhall in 1976 (reported three cases) [7], Rohatgi and Gorthi in 1984 [8], Gvalani et al., in 1985 [9], Mohite et al., in 2007 [10], Zea et al., in 2009 [11], Agrawal and Memon in 2010 [12], Singh et al. in 2011 [13], Pauleau et al., in 2012 [14], Patel et al., in 2013 [15] and Kadian in 2015 [16]. Moreover, to the best of our knowledge there is no reported case of a new born presenting with patent VID with prolapsed (intussusceptions) of proximal and distal ileal loop.

Antenatal diagnosis of a PVID anomaly can be confused with hernia of the umbilical cord or exomphalos minor which fails to obliterate on serial ultrasonography. Early diagnosis of PVID anomalies mandates surgeons to have a high index of suspicion in suspected cases. This would lead to prompt diagnosis and management of this rarity and save the neonate the morbidity and mortality associated with subsequent intestinal obstruction and ischemia.

As noted in the previous case reports on the topic [1,2,17], outcome is highly dependent on time of presentation, early diagnosis, associated anomalies and the size of defect. When patients present late the approach must be more conservative with formal laparotomy and or ileostomies. However, if patients present early a trans umbilical approach can be taken comfortably with good outcomes. Clinicians especially general practitioners need to be vary of a possible VID malformation in susceptible neonates in their presentation with intermittent discharge from the umbilicus.

It is the widely patent type of PVID which are more likely to present with either complete or partial prolapse of ileum through the defect. The prolapse itself is probably caused by a sudden increase in intraabdominal pressure associated with straining in neonates with a widely patent VID. Moreover, since the distance between the ileocecal valve and VID is shorter in neonates it leads to higher intraluminal pressure causing double intussusception [16].

Resection and anastomosis is preferable to wedge resection of PVID because of the associated risk of ectopic gastric or pancreatic
mucosa as well as the associated ischemia secondary to intestinal obstruction and strangulation [17].

We believe that this is a neonatal emergency which must be dealt with urgently due to the associated intestinal obstruction from intussusception, strangulation and gangrene of the prolapsed intestinal loop. In our case, we were able to do a primary closure of the VID following reduction of the prolapse due to the early presentation of the patient. Transumbilical approach was also possible because of the early presentation with good cosmetic outcome.

All reported cases before this presented during late neonatal period or infancy. This patient however, presented with it from the time of birth, which makes us wonder whether perinatal events lead to its earlier presentation or was it a prenatal event. Therefore, clinician must have a very high index of suspicion for diagnosing it timely, though its management will always follow principals of standard neonatal bowel surgery.

4. Conclusion

Patent vitellointestinal duct with prolapsed (intussusceptions) of both proximal and distal ileal loop is a very rare occurrence together with being a neonatal surgical emergency due to the associated morbidity.

Conflict of interest

None.
