THE act of mating affects insect reproduction in several ways\textsuperscript{1}. First, it may be a necessary stimulus for the initiation of oocyte development, as is found in the bedbug, \textit{Cimex lectularious}\textsuperscript{2}. Second, the act of mating may set in motion an accelerated rate of egg maturation\textsuperscript{3}. Third, copulation may induce oviposition rather than affect the processes leading to the attainment of full-term eggs; for example, in the mosquito, \textit{Aedes aegypti}, blood-fed virgin females produce about the same number of mature eggs as mated females, but most of these are not deposited\textsuperscript{4}. Finally, the act of mating may not have any apparent effect at all, either on egg development or egg deposition: at least one recent example of this, that of the cotton stainer, \textit{Dysdercus fastiatus}, is well documented\textsuperscript{5}.
