

ESTIMATION OF AGE DISTRIBUTIONS, CENSUS COVERAGE  
AND DEATH REGISTRATION COMPLETENESS IN KENYA

BY

MONICA AKINYI MAGADI

THIS THESIS HAS BEEN ACCEPTED FOR  
THE DEGREE OF M.Sc. (1990)...  
AND A COPY MAY BE PLACED IN THE  
UNIVERSITY LIBRARY.

UNIVERSITY OF NAIROBI  
LIBRARY

THIS THESIS IS SUBMITTED IN PARTIAL FULFILMENT OF THE DEGREE OF  
MASTER OF SCIENCE IN POPULATION STUDIES AT THE POPULATION STUDIES  
AND RESEARCH INSTITUTE, UNIVERSITY OF NAIROBI.

UNIVERSITY OF NAIROBI LIBRARY

**DEDICATION**

This thesis is dedicated to my husband, Joseph Ponono Magadi

**ACKNOWLEDGEMENT**

I am greatly indebted to my sponsors, University of Nairobi, for awarding me the scholarship that has enabled me undertake a full time study for the degree of Master of Science in Population Studies. I owe my most profound appreciation to Professor J. A. M. Ottieno, my principal supervisor, for his technical guidance, keen supervision and continuous encouragement throughout the course of this study. I also wish to thank my other supervisors Professor C.Hammerslough and Dr Z. Muganzi for their valuable contributions that made the completion of this study a success. The co-operation and constructive criticisms offered by the staff and the students of the Population Studies and Research Institute, cannot escape my heartfelt appreciation.

Last but not least, I acknowledge the encouragement, moral support and patience of my family - my husband Joseph and children: John Paul, Antoinette and Immaculate.

**ABSTRACT**

This thesis has examined two aspects of demography, namely; the completeness of death registration and relative coverage of censuses in Kenya at the national level and by sex. The data used was the 1969 and 1979 censuses and the death registration during the period between 1969 and 1979. Two techniques were used, namely; Hill's version of the generalized growth balance technique and the Palloni - Kominski forward - backward projection method.

The results showed that the completeness of death registration was 26.18 percent for males and 18.25 percent for females using Hill's technique. The Palloni - Kominski method gave relatively lower death registration completeness of 19.39 percent for males and 14.50 percent for females. The relative coverage of the the 1979 census with respect to the 1969 census was 98.79 percent for males and 97.11 percent for females by the Hill's technique. Using the Palloni - Kominski method, however the coverage was 103.58 percent for males and 100.57 percent for females.

The second aspect of the thesis was the detection and correction of errors due to age misreporting. For detection, the age ratio technique and the age specific growth rate technique were used. For correction, the Demeny - Shorter method and the Saxena - Gogte method were used. Having corrected the errors due to age misreporting individually and jointly, then the age specific growth rate technique was again applied to the corrected data for

a check up. The effect of changes in census coverage, mortality level and life expectancy at old age was also looked into.

## CHAPTER 1

### THE GENERAL INTRODUCTION

#### 1.1 INTRODUCTION

Demographic data compiled by national population censuses in the developing countries are often subject to a number of limitations resulting from age misreporting and coverage errors. The inadequacy of the age statistics can generally be attributed to one or both of two basic sources, namely; failure to report ages, (or) mis-statement of ages that are reported. When the former occurs, and the proportion of unknown ages is significantly large, not much can be done unless the researcher has access to other data that would provide a basis for a realistic distribution of unknowns among the population with known ages. However, in most cases, the problem of unknown ages is secondary and it is errors in the ages reported that constitute the most serious source of bias in age data.

#### 1.2 STATEMENT OF THE PROBLEM

One of the major difficulties in African population censuses and surveys is the measurement of age. The problem is not simply one of vagueness or digit preference by the respondent but more commonly of complete ignorance. The enumerator frequently has to make an estimate from appearance, memories of events, and marital status, among others. An examination of age distributions obtained in African censuses revealed great and systematic

distortions (Brass and Coale, 1968). Several methods of estimating demographic parameters for developing countries depend on the relation between two age distributions. Age misreporting and variations in census coverage distort this relation and introduce biases in the estimate. Demographers have, therefore, made available several methods for graduating age distributions to make them conform to certain patterns of stable models on the assumption that deviations from these patterns are due to error. The main danger in applying this procedure is in imposing an unrealistic model on the data and thus mistaking inherent features as errors. Age errors are not always easy to detect and may be very difficult to measure. In a number of demographic studies that have been carried out using Kenyan age data, the authors have merely mentioned that the data is of poor quality, but no real systematic work has been done in detecting and making appropriate adjustments for the existing errors.

### 1.3

#### OBJECTIVES OF THE STUDY

The main objective of the study, therefore, is to estimate age distributions, census coverage and death registration completeness in Kenya. Specifically, the purpose of the study is to (a) estimate the relative completeness of the 1979 census coverage with respect to the 1969 census coverage; (b) estimate the completeness of death registration in Kenya during the period 1969-1979; (c) identify the nature and extent of age misreporting

errors in Kenyan data by applying various techniques of detecting age misreporting; and (d) make appropriate adjustments for age misreporting errors, and thus attempt to estimate Kenya's age distribution.

#### 1.4 STUDY RATIONALE / JUSTIFICATION

There are clearly many biases involved at various stages of data collection and analysis, and users of the data need to recognise the presence of biases and the potential distortions of various measurements. Information on age is a basic variable in constructing many demographic parameters. Errors in reported age distributions affect the estimation of demographic measures, especially in the developing countries. The reliability of the derived estimates for these countries depend to a large extent on the degree of error and bias inherent in the age reporting of their populations. An evaluation of the nature and extent of distortions in reported age data will alert users of the data to their limitations and provide a guide to future census operations in the country. Improved knowledge on the distribution by age and its biases should, therefore, rank high in the order of priorities in African demography, since no thorough demographic analysis is possible without it.

It should also be recognised that mortality estimates are not only important in estimating population growth, but are also valuable indicators of public health achievement and level of socio-economic development. The analysis of mortality, therefore, is an indispensable part of informed decision making

and evaluating public policies, including life insurance. For this reason, it is essential that attempts be made to obtain mortality estimates of the highest possible degree of accuracy. It is, therefore, necessary that errors in mortality data, such as the degree of incompleteness of death registration be identified.

#### 1.5 SCOPE AND LIMITATION OF THE STUDY

Since most of the techniques to be employed in this study are based on the assumption that the population under study is closed to migration, the study will only be carried out at the national level, migration being insignificant at this level. Methods for making appropriate adjustments for the effect of migration may be available, but their application to data at district level is hindered by the limited amount of time available for this study. The study will utilize secondary data obtained from censuses and vital death registration. Specifically, the study will make use of single and five-year age distributions of the 1969 and 1979 population censuses classified by sex and the 1969, 1974 and 1979 death registration by five-year age groups and by sex.

#### 1.6 LITERATURE REVIEW

The literature review has been split into three categories. The first category deals with studies on detecting age misreporting while the second category focuses on methods of correcting age distributions; and, finally, the last category giving techniques of estimating completeness of death registration, and census enumerations.

Existing analytic techniques of detecting age misreporting are of several types. The first type consists of indices of digit preference for each digit. Myers (1940) proposed the measure still most frequently used while Bachi (1951) and the United Nations (1961) put forward variants of Myers' approach. The second type of measures consist of summary indices of digit preference or undifferentiated age misstatement. Marten (1924) made use of the index known as Whipple Index. Myers (1940) presented a summary index derived from his indices of preference for each digit. An index of all types of age misstatement was proposed by the United Nations (1955) and a variant by Das Gupta (1955). Barclay (1958), however, observed that a demographic analyst is not really interested in an index of digit preference for the entire age distribution since some parts are more likely to be of more interest than the whole.

Nagi, Stockwell and Snavley (1973) examined the extent of digit preference and avoidance in the age statistics of African censuses, paying particular attention to identifying some of the social and economic correlates of age heaping. They calculated age ratios to detect age heaping at particular ages and applied Myers' (1940) blending technique to the single year age statistics of selected 31 African nations, by socio-economic differentials. The same technique was later applied to World Fertility Survey (WFS) data from various regions, namely: Nepal (Goldman, Coale and Weinstein, 1979), Mexico (Ordorica and Potter, 1981), Jordan (Blacker, Hill and Moser, 1983), Ghana

(Owusu, 1984), Cameroon (Santow and Bioumla, 1984) and Lesotho (Timaues and Balasubramanian, 1985). Apart from using Myers' blending technique, detection of age misreporting in the WFS data was also achieved through: examination of single-year and five-year age group distributions as fitted by stable population distributions; use of Whipples, United Nations and rectangular indices; matching of age reports; and examination of age-sex pyramids and sex ratios.

Nagi and associates (1973) observed that the degree of heaping was more pronounced for the Islamic than non-Islamic regions. Age heaping was also observed to be greater for females than males. Apart from a few exceptions, digit preference was found to increase with age and conformed to the following pattern, namely; 0 was the most preferred, followed by: 5, 2 and 8, 4 and 6, 3 and 7, and finally, 1 and 9 were the most avoided. These results were consistent with the findings of the pattern of age misreporting in the WFS data. It was also observed that greater accuracy in age reporting was associated with higher level of socio-economic development.

Techniques for smoothing age distribution data by graduating five or ten-year age groupings and interpolating for single years had been presented by Bachi (1951), Jaffe (1951), Wolfenden (1954), Carrier and Farrag (1955), and Shryock and Siegel (1971). Such methods are open to the criticism that no graduated series can properly be assumed to be a representation of the numbers which should have been recorded in the sense that the difference between the graduated and the ungraduated series are only

misstatement of age. Furthermore, different methods of graduation vary greatly in their smoothing power, and may produce very different estimates of error (Wolfenden, 1954).

Demeny and Shorter (1968) devised a special method of correcting age misreporting that could separate true irregularities from reported errors. The method is based on the following assumptions: (a) the pattern of age misreporting is systematic and repeats itself from one census to the next; (b) the population is assumed to experience an appropriate mortality schedule; and (c) the total population was enumerated correctly, or at least that the coverage of the two censuses was reasonably close. The correction factors obtained after applying this technique to the pairs of Turkish censuses for 1935-40 and 1955-60 provided the following information about age misreporting: The ages of young children were exaggerated, causing a relative deficit at ages 0-4 and contributing to an excess at ages 5-9. This was true for both sexes. Women near the age of puberty and early marriage tended to exaggerate their ages once these events were passed and this depleted the reported size of the 10-14 and 15-19 age groups. They continued to be transferred upwards across the age boundaries at 25 and 30, causing excessive proportions to be reported at ages 25-29 and 30-34. For males, the pattern of misreporting indicated smaller errors and a different progression of the events which influenced judgement on age. This was attributed to higher male literacy and the importance of age in determining the time for military service. The fact that males were transferred downwards across the

boundaries at ages 15 and 20 could have been due to a tendency to assign lower than true ages to men who were later than usual in maturing physically or performing military service. The errors at ages above 40 for both sexes had a saw-tooth pattern, containing a relatively large component of digit preference at multiples of 10. Since the pattern of errors was so closely similar for the pairs of censuses separated by 20 years, the assumption that systematic repetitive error occurred appeared to be fully supported.

Das Gupta (1975) observed that the Demeny-Shorter method gave excellent results when the true age distributions for the two censuses were identical or reasonably close. However, as the disparity between them widened, it became increasingly difficult for the method to satisfy simultaneously the three underlying assumptions. To remove this limitation, Das Gupta modified the method by relaxing the first assumption while keeping the other two unchanged. This method, though more complicated, is always consistent, irrespective of the population under consideration (Das Gupta, 1975).

Ntozi (1978) presented a method based on the same idea as the Demeny-Shorter method but utilizing three instead of two successive censuses. Unlike the Demeny-Shorter method which assumed same coverage and similar pattern of age misreporting for the two censuses, the three census method allows for, and estimates the likely changes in census coverage and different patterns of age errors in successive censuses. Unfortunately, the

method is restricted to countries with three censuses which must be of equal intervals. Furthermore, a comparison of results with the Demeny-Shoter method showed that the correction factors from the two methods were reasonably close in many age groups and the pattern of age errors disclosed by the two approaches similar. He, therefore, stated that the Demeny-Shorter assumptions were reasonably accurate with regard to age misreporting.

Saxena and Gogte (1985) investigated the possibility that a simpler procedure, for correcting age heaping on multiples of five, could yield equally effective results as the Feeney's (1979) procedure. A nine-point moving average was selected for comparison. The nine-point moving average was applied once (method A), then twice (method B) to census age distributions for India (1971), Tanganyika (1967) and Indonesia (1971), and results compared with those obtained by applying Feeney's method (method C). The results showed that all the three methods performed equally well for the three countries considered. They concluded that method A is more preferable, because it is the simplest to apply.

Gray (1987) presented a new method for adjusting age distributions to remove the effect of digit preference, by modifying Zelnik's (1961) procedure. For practical applications attention was restricted to Q1 and Q2 operators. Census age-sex pyramids for Bangladesh (1974), Libya (1973) and Australian Aborigines (1981) were transformed using Q1 and Q2 linear operators. A comparison of results appeared to favour use of Q2 rather than Q1, although there was virtually no difference in the

case of Australian Aboriginal data, which had least irregularities in the beginning. Gray, therefore, suggested that slightly irregular data may be adjusted adequately with the Q1 operator, but greater irregularities require use of Q2 operator to obtain adequate results. He claimed that the method is easy to use and superior to graduation methods in that it is based on a specific model of age misstatement and age pyramid shape, and superior to Zelnik's approach in that the pattern of age misstatement is more clearly specified and the method is biased in less restricted conditions.

No real systematic work has been done in detecting and making appropriate adjustments for age misreporting in Kenya. However, Rono (1982) assessed the quality of age reporting in the 1969 and 1979 censuses using United Nations summary index (United Nations, 1955), Myers' summary index, and Whipple indices for the ten terminal digits. He observed that the quality of age reporting, judged by the extent of digit preference, was quite poor and more pronounced for the females. Heaping was observed to be more substantial for terminal digits 0, 5 and 8 in that order.

Over the last few years, there has been a considerable amount of research on techniques of estimating the completeness of adult death registration from incomplete and inaccurate vital statistics. Around 1980, three methods were proposed to relax the assumptions of stability in the growth balance equation developed by Brass (1975) to estimate the completeness of death registration relative to the completeness of census coverage.

Martin (1980) generalised the growth balance equation by allowing the growth rate to vary with age. No explicit allowance was made, however, for the possibility that the two censuses could be of different coverage. Preston and Hill (1980) and Brass (1979) proposed methods that sought specifically to estimate the relative coverage of two census enumerations and the completeness of death registration, relative to one census or the other.

The Preston-Hill procedure relies on the fact that in the absence of age misreporting, the intercensal survival ratios constructed from enumerated populations are related to the cohort intercensal death rates. Regretably, even after cummulation is used, the procedure remains very sensitive to age misreporting and frequently produces implausible results. Palloni and Kominski (1984) reconstructed the population-based survival ratios with the aid of foward and backward projections in order to minimise the effects of age misreporting. They applied the procedure to the female populations of El Salvador (1961-71) and Honduras (1961-71) and tested the completeness of death registration and census coverage estimates for both internal and external consistency. The estimates obtained by applying the foward and backward projections were observed to be more reliable than those obtained by Preston-Hill method, less variable than those generated by Bennett-Horiuchi (1981) procedure, and consistent with estimates generated by Preston-Bennett (1983) or maternal orphanhood techniques.

Hill (1987) presented a new method for estimating the relative completeness of two census enumerations and of intercensal deaths

by extending Martin's (1980) formulation. Whereas Brass (1979) used deaths by cohorts, in Hill's study, deaths by age group rather than deaths by cohort were used on the grounds that age group comparisons would be less distorted by age misreporting than cohort comparisons, if the patterns of age misreporting were similar for the two successive censuses. The method was applied to the female population of South Korea in 1970 and 1975 censuses, and registered deaths in the period 1971 to 1975. The obtained estimates of completeness indicated that the 1975 census was 0.45% more completely enumerated than the 1970 census and registration of deaths was 62.6% complete. Using the Bennett-Horiuchi method, death registration completeness had been obtained to be 65%. Hill's explanation for the difference in the two estimates of completeness of death registration was that higher enumeration completeness at the second census would inflate the age specific growth rates. In the Bennett-Horiuchi formulation, this exaggeration of growth rates would increase the population at each age,  $a$ , calculated from deaths and growth rates over age  $a$ , and this would make registered deaths appear to be more complete than they actually are. Hill stated that, compared to the Bennett-Horiuchi procedure which uses age specific growth rates to assess completeness of death registration, his method is free from inconvenient assumptions about the open interval or distribution of deaths within age groups.

In Kenya, Nyokangi (1984) and Kizito (1985) applied the Bennett-Horiuchi technique to estimate the completeness of death

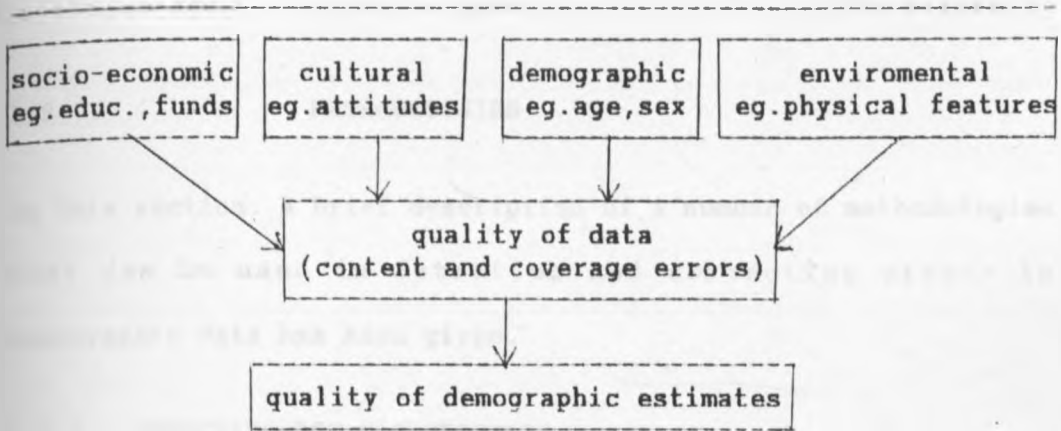

registration in 1979. They used the 1969 and 1979 census data as well as the 1979 vital death registration data. Nyokangi carried out his study at the national level and observed that the completeness of death registration was as low as 22% for males and 13% for females. Kizito's study, which was carried out at district level, revealed that differentials in mortality existed by districts, and also confirmed better death registration data for males as compared to females.

### 1.7 THEORETICAL FRAMEWORK

From the foregoing literature review, and several other studies that have been conducted to assess the quality of demographic data, it is evident that data from the developing countries suffer from severe content and coverage errors. Under content errors, the most serious is age misreporting which takes the form of: age heaping on particular preferred digits, or systematic age transference across age group boundaries. The most common source of age misreporting is illiteracy of the respondent, leading to estimation of age by the respondent or by the interviewer based on external clues. Age heaping has been observed to increase with age and, in most cases, more pronounced for females than for males. Frequently, age exaggeration or heaping at particular age groups has been observed to reflect the importance attached to various age groups by the society. Lack of written records, poor training of enumerators, short interview time, and poor supervision also contribute to the poor quality of demographic data in the developing countries. Event displacement

and omission of vital events has frequently been observed when analysing maternal history data from various countries (Potter,1975; Brass,1978). Coverage errors often result from: either failure to cover the entire geographical region, due to socio-economic and enviromental factors or inaccurate enumerations resulting from omissions or double counting. Under-enumeration has been observed to decrease with age and, in most cases, more pronounced for females than for males. Often, it is difficult to tell the extent of each kind of error since coverage errors also distort age distributions. Futhermore, it has been observed that further errors in the data may be introduced by the data processing procedures. In short, it has been observed that socio-economic, cultural, demographic and enviromental factors either directly or indirectly influence the quality of data obtained in censuses or surveys. Errors in these data will in turn affect the demographic estimates derived from them either directly or using indirect estimation techniques.

FIGURE 1:1. A DIAGRAM SUMMARISING THE PROPOSED RELATIONSHIP BETWEEN THE CONCEPTS

Source: compiled by the author

This study will only focus on the content (age misreporting) and coverage (census coverage and completeness of death registration) errors. The following conceptual hypotheses will be tested in the study, namely; (a) the pattern of errors is systematic and repeats itself from one census to the next; and (b) demographic data in the developing countries suffer severe content and coverage errors.

### 1.8 OPERATIONAL HYPOTHESES

- (1) The degree of census coverage in the 1969 and 1979 census were reasonably close.
- (2) The degree and nature of age heaping in the 1969 and the 1979 censuses were reasonably close.
- (3) During the period 1969 - 1979, only less than a quarter of all deaths were registered.
- (4) The degree of age misreporting increases with age.

(5) Age misreporting in Kenya includes considerable age transfer across age group boundaries.

## 1.9

### METHODOLOGIES

In this section, a brief description of a number of methodologies that can be used in detecting and correcting errors in demographic data has been given.

#### 1.9.1 DETECTING AGE MISREPORTING

##### 1.9.1.1 Myers' Index

Myers' (1940) technique derives a 'blended' population which is essentially a weighted sum of the number of persons reporting ages ending in each of the ten terminal digits. The underlying assumption of this method is that if there are no systematic irregularities in the reporting of age, then the 'blended' sum of each terminal digit should be approximately equal to 10% of the total 'blended' population. If the sum at any given digit exceeds 10% of the total 'blended' population, it indicates preference of ages ending in that digit. The converse indicates avoidance of ages ending in that digit. An overall measure of the extent to which there is digit preference and/or digit avoidance is obtained by taking one-half of the absolute sum of the deviations for each of the ten terminal digits.

##### 1.9.1.2 Age Ratio

An age ratio for a specific age is computed by taking the ratio of the number reporting that age to the arithmetic mean of the

five ages immediately below and five ages immediately above the age in question. An age ratio less than one indicates avoidance for that age, whereas an age ratio greater than one indicates preference for that particular age.

### 1.9.1.3 Whipple's Index

Whipple's index may be used to measure the degree of age heaping on the terminal digits 0 and 5. The index is derived by comparing the sum of the population at ages ending in 0 and 5 with one-fifth of the total population.

### 1.9.1.4 United Nations age/sex Index

This is one way of detecting and measuring the overall extent of age misreporting by examining the age and sex ratios of the population under study and calculating an index of age accuracy from the regularity of these ratios. The index is three times the mean difference in sex ratios, plus the mean of the male and female age ratios.

### 1.9.1.5 The Age Specific Growth Rate Technique

Let  $T(x)$  be the person-years lived by those aged  $x$  years and above. Then the ratio  $T(x)/T(5)$  or  $T(x)/T(10)$  is a useful tool in detecting age misreporting.

Let  $C(x, x+5)$  be the proportion of people between ages  $x$  and  $x+5$

$r(x, x+5)$  be the growth rate for those aged  $x$  to  $x+5$  years

$L(x, x+5)$  be the person years lived between ages  $x$  and  $x+5$

Then,

$$L(x, x+5)/L(0, 5) = C(x, x+5)/C(0, 5) \cdot \exp\{2.5r(0, 5) + 5[r(5, 10) + \dots + r(x-5, x)] + 2.5r(x, x+5)\}.$$

$T(x)/L(0,5)$  is obtained by adding the column of  $L(x,x+5)/L(0,5)$  from down.

Then  $T(x)/T(5)=[T(x)/L(0,5)]/[T(5)/L(0,5)]$ .

and  $T(x)/T(10)=[T(x)/L(0,5)]/[T(10)/L(0,5)]$ .

From the Office of Population Research, Princeton University, computerized tables of  $T(x)/T(5)$  and  $T(x)/T(10)$  against mortality levels have been made for each region (East, West, North and South) and sex. A graph of age against mortality levels is then plotted. It is hypothesized that if the graph is rising, then there is an indication of overstatement of age. A graph showing a downward trend implies under-estimation of age, and a horizontal graph implies correct age statement.

## 1.9.2. CORRECTING AGE DISTRIBUTIONS

### 1.9.2.1 Demeny-Shorter Method

Starting with adjacent pair censuses, the youngest five-year age group in the first census is projected to the next census using an assumed mortality schedule. The projection is accepted as a preliminary estimate for that cohort on the second date. The ratio of this preliminary estimate to the reported provides a correction factor which is then used to correct the population in that age group at the date of the first census. Thus, it is assumed that errors are a stable fraction of the reported population in each age group from one census to the next. The corrected age group in the first census is then used as a basis for projecting to the next census, and the foregoing procedure is repeated all the way through the age distribution. The resulting figures for the two censuses are finally scaled to agree with the

total size of the population as enumerated.

### 1.9.2.2 Saxena-Gogte Method

This is a simplification of Feeney's (1979) method of correcting age distributions for heaping on multiples of five.

Let  $P(x)$  - number of persons aged  $x$  in completed years

$P(x-)$  - number of persons aged  $x-4$  to  $x-1$

$P(x+)$  - number of persons aged  $x+1$  to  $x+4$

$Dx$  - the constant of proportionality

Then, for  $Dx=1$ , Feeney's procedure will imply that:

$$1/9[P(x-)+P(x)+P(x+)] = 1/8[P(x-)+P(x+)]$$

The quantity on the left hand side is a 9-point moving average and the quantity on the right hand side is an 8-point moving average that excludes  $P(x)$ . For the two quantities to be equal, the final adjusted value of  $P(x)$  must be equal to a 9-point moving average of the final adjusted values of  $P(x-)$ ,  $P(x)$  and  $P(x+)$ . This suggests that a 9-point moving average, or its repeated application, might yield approximately the same results as the Feeney's procedure.

### 1.9.2.3 Gray's Method

This is a simplification of Zelnik's 2\*10-term moving average of adjusting for digit preference, by replacing the assumption of local linearity with an assumption that the underlying smooth age distribution curve may have upto two turning points. Gray replaced the linear operator,  $S$ , used by Zelnik, with an unbiased operator,  $Q_k=(k+1)S-kS$  for  $k>0$ . For practical applications,  $Q_1=2S-S$  and  $Q_2=3S-2S$  should be used.

### 1.9.3 ESTIMATION OF COMPLETENESS OF DEATH REGISTRATION AND CENSUS COVERAGE

#### 1.9.3.1 Palloni-Kominski Method

Palloni and Kominski modified the Preston-Hill method of estimating the relative coverage of two census enumerations and the completeness of death registration, by reconstructing the population-based survival ratios with the aid of forward and backward projections, in order to minimise the effects of age misreporting. If the degree of coverage for the two censuses is not the same, forward or backward projections cannot by themselves retrieve the correct mortality experience to which the population was exposed during the intercensal period. However, joint information provided by both types of projections, on one hand, and by the registered deaths, on the other hand, may provide good estimates of death registration completeness.

#### 1.9.3.2 Hill's Procedure

The growth balance equation was developed by Brass (1975) to estimate the completeness of death registration, relative to the completeness of enumeration of a census. Martin (1980) generalised the growth balance equation by allowing the growth rate to be age specific. Hill's formulation is an extension of Martin's equation to allow explicitly for, and estimate changes in census coverage. The method assumes that the population is closed to migration and that the coverage factors involved are invariant with age, at least for the age range studied.

## CHAPTER 2

### COMPLETENESS OF DEATH REGISTRATION AND CENSUS COVERAGE

2.1.

#### INTRODUCTION

Population censuses and vital registration systems, particularly in the developing countries are often subject to omissions. A well - conducted census will enumerate all but a few percent of the population, and it is rare for a census to enumerate less than 90 percent of the target population. In contrast, the completeness of death registration varies widely, with many systems in the developing countries registering less than half of all the deaths that occur in the population (Hill, 1987). Where substantial omissions are suspected, it is necessary to assess the coverage of the census and death registration data. In this chapter, the completeness of death registration in Kenya and the degree of the 1979 census coverage, relative to the 1969 census coverage are estimated using two methods, namely: The Palloni - Kominski method and Hill's extension of the generalized growth balance equation.

2.2.

#### HILL'S TECHNIQUE

##### 2.2.1 THE THEORY

Hill's method of estimating census and death registration completeness is an extension of a generalization of the growth balance equation developed by Brass (1975). Based on the assumptions that the: (i) population was closed to migration;

(ii) population was demographically stable; (iii) completeness of death registration was constant for all ages after early childhood; and (iv) completeness of census coverage was constant for all ages, Brass proposed the following relationship:

$$\frac{N(x)}{N(x+t)} = r + \frac{D(x+t)}{N(x+t)} \quad (2.2.1)$$

Where:

$N(x)$  is the true density of the population at exact age  $x$ ,

$N(x+t)$  is the total population above age  $x$ ,

$r$  is the stable population growth rate, and

$D(x+t)$  is the true total deaths at ages  $x$  and above.

Modifications have been made on the growth balance equation by Martin (1980), Preston and Hill (1980), and Brass (1979). Martin generalised the growth balance equation by allowing the growth rate,  $r$ , to vary with age. Thus, equation (2.2.1) becomes:

$$\frac{N(x)}{N(x+t)} = r(x+t) + \frac{D(x+t)}{N(x+t)} \quad (2.2.2)$$

Hill's method may be seen as an extension of Martin's formulation to allow explicitly for changes in census coverage.

$$\text{Thus } D'(x) = k.D(x+t) \quad (2.2.3a)$$

$$N_1'(x) = k_1.N_1(x) \quad (2.2.3b)$$

$$\text{and } N_2'(x) = k_2.N_2(x) \quad (2.2.3c)$$

Where the subscript (') denotes the observed quantities and the completeness factors  $k$ ,  $k_1$  and  $k_2$  represent completeness of death registration, coverage of first census and coverage of the second census, respectively.

We wish to express equation (2.2.2) in terms of the observed values as follows:

$$\text{from } r(x+t) = \frac{\text{Log } N_2(x+t) - \text{Log } N_1(x+t)}{t_2 - t_1}, \quad (2.2.4a)$$

We have,

$$\begin{aligned} r(x+t) &= \frac{\text{Log } [N_2'(x+t)]/k_2 - \text{Log } [N_1'(x+t)]/k_1}{t_2 - t_1} \\ &= \frac{1}{t_2 - t_1} \text{Log } \left( \frac{k_1}{k_2} \right) + \frac{\text{Log } N_2'(x+t) - \text{Log } N_1'(x+t)}{t_2 - t_1} \end{aligned}$$

Thus,

$$r(x+t) = \frac{1}{t_2 - t_1} \text{Log } \left( \frac{k_1}{k_2} \right) + r'(x+t) \quad (2.2.4b)$$

Next, using the definitions of a geometric mean and of  $N(x)$ ,

$$\begin{aligned} N(x) &= t \cdot \text{SQRT} [N_1(x) \cdot N_2(x)] = t \cdot \frac{\text{SQRT} [N_1'(x) \cdot N_2'(x)]}{k_1 \cdot k_2} \\ &= \frac{t}{\text{SQRT} [k_1 \cdot k_2]} \text{SQRT} [N_1'(x) \cdot N_2'(x)] \end{aligned}$$

Where  $N(x)$  is the population having  $x$ th birthday during the intercensal period.

$$\text{Thus, } N(x) = \frac{1}{\text{SQRT} [k_1 \cdot k_2]} N'(x) \quad (2.2.5a)$$

$$\text{and } N(x+t) = \frac{1}{\text{SQRT} [k_1 \cdot k_2]} N'(x+t) \quad (2.2.5b)$$

$$\text{Where } N'(x+t) = t \cdot \text{SQRT} [N_1'(x+t) \cdot N_2'(x+t)] \quad (2.2.5c)$$

To obtain  $N(x)$  from 5-year age groups, we recall that:

$$\begin{aligned} 5N_x &= \text{SQRT} [5N_1(x) \cdot 5N_2(x)] \\ &= \text{SQRT} \left[ \frac{5N_1'(x) \cdot 5N_2'(x)}{k_1 \cdot k_2} \right] \end{aligned}$$

$$= \frac{1}{\text{SQRT} [k_1.k_2]} \text{SQRT} [5N_1'(x).5N_2'(x)] \quad (2.2.6a)$$

This implies that:

$$5N(x-5) = \frac{1}{\text{SQRT} [k_1.k_2]} \text{SQRT} [5N_1'(x-5).5N_2'(x-5)] \quad (2.2.6b)$$

Thus,

$$N(x) = \frac{t}{5} \text{SQRT} [5N(x).5N(x-5)] \quad (2.2.6c)$$

Substituting (2.2.6a) and (2.2.6b) into (2.2.6c) gives:

$$N(x) = \frac{t}{5\text{SQRT} [k_1.k_2]} \text{4TH ROOT OF } (5N_1'x.5N_2'x.5N_1'x-5.5N_2'x-5)$$

$$\text{i.e. } N(x) = \frac{1}{\text{SQRT} [k_1.k_2]} . N'(x)$$

$$\text{Where } N'(x) = \frac{t}{5} \text{4TH ROOT OF } (5N_1'x.5N_2'x.5N_1'x-5.5N_2'x-5) \quad (2.2.7)$$

It should be noted that in Hill's (1987) work,  $t.5N(x-5)$  is denoted by  $\text{PYL}(x-5, x)$  and  $t.5N(x)$  is denoted by  $\text{PYL}(x, x+5)$ , where  $t$  is the intercensal period and  $\text{PYL}(x-5, x)$  and  $\text{PYL}(x, x+5)$  are the intercensal person years lived by the age groups  $(x-5, x)$  and  $(x, x+5)$  respectively.

Equations (2.2.5a) and (2.2.5b) imply that:

$$\frac{N(x)}{N(x+t)} = \frac{N'(x)}{N'(x+t)} \quad (2.2.8)$$

and using (2.2.3a) and (2.2.5b), we have:

$$\frac{D(x+t)}{N(x+t)} = \frac{\text{SQRT} [k_1.k_2]}{k} . \frac{D'(x+t)}{N'(x+t)} \quad (2.2.9)$$

Substituting equations (2.2.8), (2.2.4b), and (2.2.9) into (2.2.2) gives:

$$\frac{N'(x)}{N'(x+t)} = \frac{1}{t_2 - t_1} \log \frac{k_1}{k_2} + r'(x+t) + \frac{\text{SQRT}[k_1.k_2]}{k} \cdot \frac{D'(x+t)}{N'(x+t)}$$

Thus:

$$\frac{N'(x)}{N'(x+t)} - r'(x+t) = \frac{1}{t} \log \frac{k_1}{k_2} + \frac{\text{SQRT}[k_1.k_2]}{k} \cdot \frac{D'(x+t)}{N'(x+t)} \quad (2.2.10)$$

Where,  $t = t_2 - t_1$

Equation (2.2.10) is Hill's estimation equation.

### 2.2.2 APPLICATION OF HILL'S TECHNIQUE TO KENYA'S DATA

step 1: The reported intercensal deaths for those aged  $x$  years and above,  $D'(x+)$ , are obtained by cumulating recorded deaths by age group across the entire interval. The total deaths reported for those aged  $x$  to  $x+5$  years during the intercensal period are obtained by estimating average annual intercensal deaths and multiplying by 10, the intercensal period. Average annual inter-censal deaths are estimated by averaging registered deaths for 1969, 1974 and 1979 as shown in table 2:1 for Kenyan females.

TABLE 2:1: KENYA: CUMULATING INTERCENSAL REPORTED DEATHS OF FEMALES

age, x	(registered deaths)		(average)		5D'x	CUMULATED
	1969 (1)	1974 (2)	1979 (3)	1969-79 (4)	1969-79 (5)	D'(x+) (6)
0	9136	13047	11395	11192.67	111926.7	185810
5	579	1196	935	903.3333	9033.333	73883.33
10	185	522	456	387.6667	3876.667	64850
15	210	392	489	363.6667	3636.667	60973.33
20	246	445	488	393	3930	57336.67
25	249	489	495	411	4110	53406.67
30	225	450	473	382.6667	3826.667	49296.67
35	206	501	449	385.3333	3853.333	45470
40	198	452	398	349.3333	3493.333	41616.67
45	261	467	423	383.6667	3836.667	38123.33
50	223	517	463	401	4010	34286.67
55	136	352	366	284.6667	2846.667	30276.67
60	249	638	629	505.3333	5053.333	27430
65	161	448	491	366.6667	3666.667	22376.67
70+	882	2064	2667	1871	18710	18710

step 2: The recorded populations of 1969 and 1979,  $5N1'(x)$  and  $5N2'(x)$ , are entered into columns (1) and (2) as shown in table 2:2, and these are cumulated from down to give columns (3) and (4) respectively.

step 3: The  $r'(x)$  values in column (5) of table 2.2.2a are calculated from formula (2.2.4b).

$$i.e \ r'(x) = \frac{1}{t} \log \left[ \frac{N2'(x)}{N1'(x)} \right]$$

e.g for  $x = 0$ ,

$$r'(0) = \frac{1}{10} \log \left[ \frac{7719947}{5460324} \right] = 0.034629$$

step 4: The  $N'(x)$  values in column (6) are calculated from formula (2.2.5c).

$$i.e \ N'(x) = t.SQRT [N1'(x).N2'(x)]$$

e.g for  $x = 0$ ,

$$N'(0) = 10.[5460324 * 7719947] = 64925658$$

step 5: The  $N'(x)$  values in column (7) are calculated from formula (2.2.7).

$$i.e N'(x) = \frac{t}{5} \text{ 4TH ROOT OF } (5N1'x - 5.5N2'x - 5.5N1'x \cdot 5N2'x)$$

e.g for  $x = 5$ .

$$N'(5) = \frac{10}{5} \text{ 4TH ROOT OF } [5N1'(0) \cdot 5N2'(0) \cdot 5N1'(5) \cdot 5N2'(5)]$$

$$= 2270108$$

TABLE 2:2: KENYA: ESTIMATING THE COMPLETENESS OF DEATH REGISTRATION AND CENSUS COVERAGE FOR FEMALES

age, x	5N1'(x) (1)	5N2'(x) (2)	N1'(x+) (3)	N2'(x+) (4)	r(x+) (5)	N'(x+) (6)	N'(x) (7)

70+	121619	149403	121619	149403	.0205754	1347970.	-

step 6: The estimation equation is:

$$\frac{N'(x)}{N'(x+t)} - r'(x+t) = \frac{1}{t} \log \frac{k1}{k2} + \frac{\text{SQRT}[k1.k2]}{k} \cdot \frac{D'(x+t)}{N'(x+t)}$$

Which is of the form:  $Y = a + bX$

Where  $Y = N'(x)/N'(x+t) - r'(x+t)$

and  $X = D'(x+t)/N'(x+t)$

The values of X and Y are given in columns (2) and (3) of table 2.3. respectively.

step 7: Columns (4), (5), (6) and (7) are used in obtaining least square estimates of a and b.

$$\text{where } a^{\wedge} = \frac{1}{t} \log \frac{k_1}{k_2} = \bar{Y} - b^{\wedge} \bar{X}$$

$$\text{and } b^{\wedge} = \frac{\text{SQRT} [k_1.k_2]}{k} = \frac{\sum (X_i - \bar{X})(Y_i - \bar{Y})}{\sum (X_i - \bar{X})^2}$$

$$\bar{X} = .0044107 \quad \bar{Y} = .0267402$$

NB:  $\bar{X}_i - \bar{X} = \bar{X}_i$  and  $\bar{Y}_i - \bar{Y} = \bar{Y}_i$ .

Setting  $k_1=1$ ,

$$b^{\wedge} = 5.398336 = 1/k * \text{SQRT}(k_2)$$

$$a^{\wedge} = .0029297 = -1/10 * \ln k_2. \quad \text{Therefore:}$$

$$\ln k_2 = -.029297, \quad k_2 = .9711277 \quad \text{and } k = .1825485$$

The foregoing procedure is repeated for Kenyan males and combined sexes to obtain tables given in appendices 1a and 1b.

Results from Hill's technique show that the relative coverage of the 1979 census with respect to the 1969 census is 97.11 percent for females. 98.79 percent for males and 98.11 percent for combined sexes. The degree of intercensal death registration completeness with respect to the 1969 census coverage is 18.25 percent for females, 26.18 percent for males and 22.37 percent for combined sexes.

THE PALLONI - KOMINSKI METHOD

2.3.

THE THEORY

2.3.1.

The Palloni-Kominski(1984) method relies on corrected (population-based) intercensal survival ratios and their linear relation with intercensal cohort specific death rates. The correction of the survival ratios depends on results obtained from foward and backward projections of two population censuses separated by five or ten years. Palloni and Kominski (1984) showed how foward and backward projections can be used to correct the set of observed survival ratios to yield estimates of completeness of death registration and census coverage.

ESTIMATION OF ADULT MORTALITY USING FORWARD PROJECTIONS.

The technique presented by Coale and Demeny (1964), is based on the assumptions that the: (i) population is closed to migration during the intercensal period. (ii) reported population in the various age categories is not severely distorted by age misstatement; and (iii) The age pattern of adult mortality conforms to a known (or assumed) pattern of mortality.

If the first two assumptions hold, then:

$$S(x) = \frac{5L(x+10)}{5L(x)} = \frac{5N2(x+10)}{5N1(x)} \tag{2.3.1}$$

where  $[5L(x+10)]/[5L(x)]$  is the ten - year survival ratio in a life table and  $[5N2(x+10)]/[5N1(x)]$  is the ratio of the actual population in the age group  $x+10, x+15$  at the time of the second census to the actual population in the age group  $x$  to  $x+5$  at the

first census. If age misreporting is mild, then the mortality level determined by the observed survival ratios will be in the neighbourhood of the "true" level of mortality applicable to the intercensal period. However, if age misreporting is severe, Coale and Demeny (1964) suggested the use of forward survival of the observed population aged  $x$  and above in the second census. A level of mortality within the assumed family is then selected so as to match the observed population aged  $x+10$  and above in the second census. The procedure may be repeated for several ages,  $x$ , and the median of the set of levels used as a final estimate of the life table applicable for the intercensal period. With the cumulation procedure, errors of age mis-statement will seriously affect the selection of a level of mortality only if they represent substantial transfer across the pivotal ages used in the cumulation. Biases in the forward projections will however still occur when there is a high rate of population growth or when there exists differential completeness in the census enumeration.

ESTIMATION OF ADULT MORTALITY USING BACKWARD PROJECTIONS.

If there is no age misreporting and the completeness of enumeration in the two censuses is similar, then the reversal of the forward projection ought to identify exactly the same level of mortality.

$$\text{i.e. } \sum_{y=x}^w 5N_2(y+10) S(y)^{-1} \text{ should equal } \sum_{y=x}^w 5N_1(y) S(y)$$

where  $S(y)$  is the schedule of ten - year survivorship ratios for the mortality level and  $w$  is the latest year to which one can survive. When the coverage of the first census is more complete than the second, forward projections will give a lower mortality level than the backward projections. The opposite occurs when enumeration in the second census is more complete.

UTILIZATION OF FORWARD AND BACKWARD PROJECTIONS TO ESTIMATE COMPLETENESS OF DEATH REGISTRATION AND RELATIVE CENSUS COVERAGE.

If the completeness of census enumeration in the two censuses is different, then the forward or backward projections cannot by themselves retrieve the correct level of mortality to which the population was exposed during the intercensal period. However, joint information provided by both types of projections on one hand, and the observed values of intercensal death rate on the other hand may produce good estimates of death registration completeness and relative coverage of censuses.

Preston and Hill (1980) suggested that in the absence of age misreporting, the intercensal survival ratios constructed from enumerated populations are related to the cohort intercensal death ratios as follows:

$$\frac{5N_2'(x+10)}{5N_1'(x)} = \frac{k_2}{k_1} - \frac{k_2}{k} d'(x) \tag{2.3.2}$$

where  $[5N_2'(x+10)]/[5N_1'(x)]$  is the ratio of the observed population in the age group  $x+10$  to  $x+15$  at the time of the second census to the observed population in the age group  $x$  to  $x+5$  at the time of the first census.  $d'(x)$  is the observed intercensal death rate for the cohort aged  $x$  to  $x+5$  at the first

census in terms of the initial population, and the completeness factors  $k_1$ ,  $k_2$  and  $k$  denote the completeness of enumeration of first census, enumeration of second census and intercensal death registration respectively.

Formula (2.3.2) can also be applied when populations are cumulated above some pivoting ages. Preston's procedure is however very sensitive to age misreporting. In order to obtain reliable estimates of  $k_2/k_1$  and  $k_2/k$  from equation (2.3.2), Palloni and Kominski showed how the observed survivorship ratios,  $[5N_2'(x+10)]/[5N_1(x)]$  can be adjusted to obtain improved estimates of  $k_2/k_1$  and  $k_2/k$ .

For every pivotal age of cumulation,  $x^*$ , one obtains an estimated level of mortality within some model of mortality schedule. This estimated level may be derived from the backward projection procedure, or in cases with age misreporting, as an arithmetic mean of the levels corresponding to forward and backward projections. Let  $\{S^*(y)\}$  denote the survival ratios associated to the level of mortality thus estimated when  $x^*$  is the pivotal age of cumulation. The reconstructed population based survival ratios,

$$CSR(x) = \frac{\sum_{y=x}^w 5N_1'(y) \cdot S^*(y)}{\sum_{y=x}^w 5N_1'(y)},$$

when regressed on  $D'(x)$ , the cumulated cohort based intercensal death rates, yield an estimate of  $k_2/k_1$  and  $k_2/k$ . Both of them

however will be in error in so far as  $k_1$  is not equal to  $k_2$  or there are errors of age misreporting. When  $k_1$  is not equal to  $k_2$ , but no errors of age misreporting exist, one can still arrive at correct estimates of  $k_2/k_1$  and  $k_2/k$ . The estimated values of  $k_2^*/k_1$  can be used to generate an artificial network of survival ratios,  $(k_2^*/k_1).S(x)$ , within the selected model and forward and backward projections repeated, new values of  $CSR(x)$  calculated and finally new estimates of  $k_2/k_1$  obtained. The iteration procedure should converge rapidly in the sense that after no more than 3 or 4 iterations, the value of the constant in the regression will differ little from the value used to generate the artificial network,  $(k_2^*/k_1).S(x)$ , employed in the corresponding iteration stage. The reciprocal of the value of the slope in the final iteration is a good estimate of the completeness of adult death registration relative to the completeness of the second census. If  $k_2$  is not equal to  $k_1$  and age misreporting exists, the above described procedure can still be employed, but with the following modifications, that the:

- (i) average level generated by both forward and backward projections is taken as the best estimate corresponding to the case when a pivotal age,  $x^*$ , is the initial age of cumulation.
- (ii) median of the levels estimated for each pivotal age,  $x^*$ , may be taken as the best estimate of the level of mortality, and the cumulated survival ratios constructed using this estimated level.
- (iii) Convergence towards a constant,  $k_2/k_1$ , cannot any longer be guaranteed. The best alternative then is to use the constant estimated in the regression equation, in which the  $CSR(x)$  have

reconstructed using the median level of mortality and then apply forward/backward projections once more to attempt a final correction when  $k_2/k_1$  is within the range of 0.98 - 1.02, and age misreporting is not too serious. This one iteration routine will be sufficient to produce an accurate estimate of death registration completeness and relative coverage of censuses.

### 2.3.2 APPLICATION OF THE PALLONI - KOMINSKI METHOD TO KENYA'S DATA

Step 1: estimating the mortality level corresponding to the forward projections

(a) The observed 1969 population aged  $x$  to  $x+4$ ,  $5N_1(x)$ , is entered into column (1) and the ten - year survival ratios for various mortality levels from the North model,  $10S(x,x+4)$ , entered into column (2) as shown in table 2:4 for Kenyan females.

(b) The projected 1979 population aged  $x+10$  to  $x+14$  years,  $5N_2*(x+10)$ , is obtained by multiplying columns (1) and (2).

These are entered into column (3).

$$\text{i.e } 5N_1(x) \cdot 10S_{x,x+4} = 5N_2*(x+10) \quad \text{e.g for } x=0,$$

$$5N_1(0) \cdot 10S_{0,4} = 5N_2*(10)$$

$$\text{i.e } 1046380 \cdot 0.82791 = 866308.4, \quad \text{for level 8, North}$$

Model - females

(c) The projected 1979 population aged  $x+10$  years and above,  $N_2*(x+10)+$ , is obtained by cumulating column (3) from down.

This is entered into column (4).

The above three steps are repeated for several mortality levels within which the mortality level of the study population can possibly lie as shown in table 2:4 below for Kenyan females.

- (e) The observed 1979 population aged  $x+10$  to  $x+14$  years.  $5N_2(x+10)$ , is entered into column (1) of table 2.6 and this cumulated from down to obtain column (2), the observed 1979 population aged  $x+10$  years and above, denoted by  $N_2(x+10)+$ .
- (f) The mortality levels corresponding to various pivotal ages of cumulation are estimated through linear interpolation, by obtaining from table 2.5 the level whose projected population corresponds to the observed population in column (2) of table 2.6 The median level for the various pivotal ages of cumulation (In our case,  $x^*$  is from 10 to 50) is taken as the level corresponding to forward projections.

MEDIAN MORTALITY LEVEL = 13.84219

step 2: estimating the mortality level corresponding to the backward projections.

As in the case of forward projections, mortality levels corresponding to the backward projections are obtained by projecting the observed 1979 population aged  $x+10$  to  $x+14$  years,  $5N2(x+10)$ , backwards to obtain the projected 1969 population. In the backward projections, the reciprocals of the ten-year survival ratios are used as shown in table 2.7 below:

Source: compiled by the author

The levels implied by the observed 1969 population aged x years and above are obtained by interpolating linearly through table 2:8. The median level for the various pivotal ages of cumulation is taken as the estimate of the level corresponding to the backward projections. These are given in table 2:9 below.

TABLE 2:9: ESTIMATING THE MEDIAN MORTALITY LEVEL CORRESPONDING TO THE BACKWARD PROJECTIONS.

x	FEMALE POPULATION ESTIMATED		
	5N1x (1)	N1(x)+ (2)	LEVEL (3)

65	63307	184926	
70+	121619	121619	

MEDIAN MORTALITY LEVEL = 9.334731

step 3: estimating mortality level for the intercensal period

The estimate of the mortality level for the intercensal period is obtained as the arithmetic mean of the median levels corresponding to forward and backward projections.

i.e MEAN OF MEDIAN LEVELS = 11.58846

step 4: Cumulating cohort deaths from registration data.

The proximate procedure for estimating cohort deaths is too crude to give reasonable results for the cohort initially aged 0 to 4, so we start with that aged 5 to 9. Registered deaths by five-year age groups in 1969, 1974 and 1979 are entered into columns (1), (2) and (3) respectively as shown below in table 2:10 for Kenyan females.

(a) Cohort deaths over the first five years, mid-1969 to mid-1974 are estimated as:

$$\begin{aligned} \sum_{j=1969}^{1974} D(5,9) &= 2.5[5D(5) + 5D(10)] \\ &= 2.5[579 + 522] = 2752.5 \end{aligned}$$

(b) Cohort deaths over the second five years, mid-1974 to mid-1979, are estimated as:

$$\begin{aligned} \sum_{j=1974}^{1979} D(5,9) &= 2.5[5D(10) + 5D(15)] \\ &= 2.5[522 + 489] = 2527.5 \end{aligned}$$

(c) Cohort deaths for the ten - year period are then obtained by summing the deaths during the two five - year periods. Thus:

$$\begin{aligned} \sum_{j=1969}^{1979} D(5,9) &= \sum_{j=1969}^{1974} D(5,9) + \sum_{j=1974}^{1979} D(5,9) = 2752.5 + 2527.5 \\ &= 5280.0 \end{aligned}$$

The results for each cohort are shown in table 2:10

(d) The only age group that requires special treatment is the open-ended interval, 60 years and above. For the period 1969 to 1974, all the yearly deaths over 65 years belong to this cohort, and some of the deaths to persons aged 60-64 years. The total number of deaths over 65 years during the 1969-74 period can be estimated by summing the deaths over 65 in 1969 and 1974 and multiplying the sum by 2.5. i.e

$$\begin{aligned} \sum_{j=1969}^{1974} (w-65)D(65) &= 2.5[(w-65)D(65) + (w-65)D(65)]. \\ &= 2.5[161 + 882 + 448 + 2064] = 8887.5 \end{aligned}$$

Where  $(w-65)D(65)$  denotes the number of deaths occurring during year  $j$  to persons aged 65 years and over.

For the age group 60-64, the average number of deaths per year between 1969 and 1974 is estimated as:  $0.5(249 + 638) = 443.5$  and since the cohort averaged 2.5 years of exposure to the risk of dying during the 1969-74 period, the deaths during this period to persons aged 60-64 belonging to that cohort are estimated as:  $2.5(443.5) = 1108.75$ . Hence, the total number of deaths for the cohort aged 60 years and above in 1969 is:

$$\sum_{j=1969}^{1974} 5D^j(60) + \sum_{j=1969}^{1974} (w-65)D^j(65) = 8887.5 + 1108.75 = 9996.2$$

Between 1974 and 1979, all the deaths at age 70 and above belong to the initial 60+ cohort, as do a proportion of the deaths 65-69.

Deaths at age 70 and over are estimated as:

$$\sum_{j=1974}^{1979} (w-70)D^j(70) = 2.5 \left[ \sum_{j=1974}^{1974} (w-70)D^j(70) + \sum_{j=1975}^{1979} (w-70)D^j(70) \right]$$

$$= 2.5[2064 + 2667] = 11827.5$$

Deaths occurring to the cohort during the 1974-79 period at ages 65-69 can be estimated from the average annual number of deaths at these ages,  $0.5(448 + 491)$ , and the average exposure to risk, 2.5 years, giving  $(2.5)(0.5)(448 + 491) = 1173.75$ . Hence, the deaths during the 1974-79 period to the cohort aged 60+ at 1969 are:

$$\sum_{j=1974}^{1979} D^j(60, w) = 11827.5 + 1173.75 = 13001.25$$

Column (6) of table 2:10 is obtained by adding columns (4) and (5), and cumulating it upwards, we get column (7), the cumulated cohort deaths for the intercensal period (1969-79).

TABLE 2:10: CUMULATING COHORT DEATHS FROM REGISTRATION DATA - FEMALES

step 5: obtaining survival ratios for the estimated level.

The survival ratios for the lower and upper levels, for example; levels 10 and 12 for Kenyan females in our case, are entered into columns (1) and (2) respectively of table 2:11.

Let X, the estimated level, lie between levels X1 and X2 and the survival ratio of level X be Y. Then the survival ratios for the estimated level may be obtained by linear interpolation as:

FIG. 1:1: ILLUSTRATION OF LINEAR INTERPOLATION

$$Y = Y1 + \left[ \frac{(X - X1)}{(X2 - X1)} \right] * (Y2 - Y1)$$

These values are entered into column (3) of table 2:11 as shown below.

TABLE 2:11: OBTAINING SURVIVAL RATIOS FOR THE ESTIMATED LEVEL.

x	LEVEL 10	LEVEL 12	ESTIMATED

step 6: estimating the completeness of death registration and census coverage

(a) The observed 1969 female population, 5N1(x), is entered into column (1) of table 2:12, and its product with column (3) of table 2:11 entered into column (2) of table 2:12.

$$i.e \ S^{\wedge}x * 5N1(x) = 5N1(x).S^{\wedge}x$$

e.g for the 0-4 age group,

$$0.882064 * 1046380 = 922974.4$$

(b) Column (3) of table 2:12 is obtained by cumulating column (2) from down. Thus:

$$cum. 5N1(x).S^{\wedge}x = \sum_{y=x}^w 5N1(y).S^{\wedge}y$$

(c) Column (4) of table 2:12 is obtained by cumulating column (1) from down. i.e:

$$cum. 5N1(x) = \sum_{y=x}^w 5N1(y)$$

(d) Column (5), the reconstructed population based survival ratios, denoted by  $CSR(x)$ , are obtained by dividing column (3) by column (4)

i.e

$$CSR(x) = \frac{\sum_{y=x}^w 5N1(y) \cdot S^y}{\sum_{y=x}^w 5N1(y)} = Y_i$$

e.g for the 0-4 age group,  $0.886337 = 4839688/5460324$

(e) column (6), the cumulated cohort based intercensal death rates, denoted by  $D^*x$ , are obtained by dividing column (7) of table 2:10 by column (4). i.e:

$$D^*x = \frac{\sum_{y=x}^w D(y)}{\sum_{y=x}^w 5N1(y)} = X_i$$

8.667182 .4902646

$\bar{X} = .0408554$

$\bar{Y} = .7222651$

(f) our basic estimation equation is:

$$\frac{\sum_{y=x}^w 5N1(y) \cdot S^y}{\sum_{y=x}^w 5N1(y)} = \frac{k2}{k1} - \frac{k2}{k} * \frac{\sum_{y=x}^w D(y)}{\sum_{y=x}^w 5N1(y)} \quad (2.3.6a)$$

which is analogous to:

$Yi = a + bxi \quad (2.3.6b)$

where  $a = k2/k1$  and  $b = -k2/k$

The values of a and b are obtained as the least square estimates of the constant and the slope of equation (2.3.6b).

$$i.e \hat{b} = \frac{\sum_{i=2}^{13} (X_i - \bar{X}) \cdot (Y_i - \bar{Y})}{\sum_{i=2}^{13} (X_i - \bar{X})^2} \quad (2.3.7)$$

$$and \hat{a} = \bar{Y} - \hat{b} \bar{X} \quad (2.3.8)$$

Equations (2.3.7) and (2.3.8) are solved simultaneously using table 2:13 below.  $\hat{a}$  gives the relative completeness of the 1979 census with respect to the 1969 census where as the negative of the reciprocal of  $\hat{b}$  gives degree of completeness of intercensal death registration, relative to 1979 census coverage.

TABLE 2:13: ESTIMATING THE COMPLETENESS OF DEATH REGISTRATION AND CENSUS COVERAGE FOR KENYAN FEMALES

age, x	$\bar{X}_i$ (1)	$\bar{Y}_i$ (2)	$\bar{X}_i \cdot \bar{Y}_i$ (3)	$(\bar{X}_i)^2$ (4)	(i) (5)

-.037135 .0053523

where  $X_i = \bar{X}_i - \bar{X}$  and  $Y_i = \bar{Y}_i - \bar{Y}$ .

Then,  $\hat{b} = -6.93806 = -k_2/k_1$ , and  $\hat{a} = 1.005722 = k_2/k_1$

Setting  $k_1=1$ . then  $k_2=1.005722$  and  $k = 0.1449570$

step 7: The iteration procedure.

The estimated values of  $k_2/k_1$  should be used to generate an artificial set of survival ratios,  $(k_2/k_1).10S(x,x+4)$ , within the selected levels from an appropriate model (In our case the North model) and forward and backward projections repeated, new values of  $CSR(x)$  calculated and finally new estimates of  $k_2/k_1$  and  $k_2/k$  obtained. When there is no age misreporting, the iteration procedure will converge rapidly to give accurate values of  $k_2/k_1$  and  $k_2/k$ . However, in our case convergence does not occur.

The foregoing procedure is repeated for the Kenyan males to give the corresponding tables, given in appendix C.

The Palloni - Kominski method does not appear to give reliable results with the Kenyan data. First and foremost, convergence, which is required for optimum accuracy, does not occur, possibly due to considerable age misreporting and/or the high rate of population growth. Secondly, the value of  $k_2/k_1$ , for the Kenyan males, lies outside the range (0.98-1.02) within which the one - iteration routine would be sufficient to produce an accurate estimate of death registration completeness. Furthermore, even though it is not the aim of this study to estimate mortality levels, the inconsistencies in the implied average mortality levels by sex of 11.59 for females and 14.26 for males, raise suspicion on the appropriateness of the method to Kenya's data. For these reasons, the iteration procedure does not help improve on the results. Results from the Palloni - Kominski method imply

that the relative coverage of the 1979 census with respect to the 1969 census coverage was 100.57 percent for females and 103.58 percent for males. The degree of intercensal death registration completeness is 14.50 percent and 19.39 percent for females and males, respectively.

## CHAPTER 3

### DETECTION OF AGE ERRORS

#### 3.1. INTRODUCTION

Age errors may be divided into two categories. The first category takes the form of age heaping on certain preferred digits or ages. The second category consists of systematic age misreporting that transfers persons across age group boundaries and may thus make the population appear older or younger than it actually is. In this chapter, detection of age errors in Kenya is carried out using two techniques, namely; the age ratio technique and the age specific growth rate technique. The age ratio technique not only detects heaping on specific ages, but may also identify systematic age misreporting. The age specific growth rate technique detects systematic age misreporting that carries people across age group boundaries.

#### 3.2 THE AGE RATIO TECHNIQUE

##### 3.2.1 THE THEORY

The commonly used indices of digit preference, namely: the Myers' Index and the Whipple's Index, provide convenient means of determining the overall extent of preference or avoidance for specific terminal digits. However, they do not take into account the possibility that heaping at any given digit may be due to a particular preference for a single age and may not really reflect any preference for the particular terminal digit. The age ratio technique determines the extent of heaping at specific

ages. The age ratio of a particular age is computed by taking the ratio of the number reporting the specific age to the arithmetic mean of the number reporting the five ages immediately below and five ages immediately above the age in question. For example, the age ratio for age 5 would be computed as the number of persons reporting age 5 divided by one-tenth of the sum reporting ages 0, 1, 2, 3, 4, 6, 7, 8, 9 and 10. An age ratio less than one indicates avoidance for that particular age, where as an age ratio greater than one indicates preference for the age in question. 5 is the lowest age for which an age ratio can be computed.

### 3.2.2 APPLICATION OF THE AGE RATIO TECHNIQUE TO KENYA'S DATA.

step 1: Let  $N'(x)$  be the enumerated population aged  $x$  years and  $R(x)$  be the age ratio for age  $x$ .

Then, using the enumerated population by single years of age,

$$R(x) = N'(x) / [(1/10) * (N'(x-5) + N'(x-4) + N'(x-3) + N'(x-2) + N'(x-1) + N'(x+1) + N'(x+2) + N'(x+3) + N'(x+4) + N'(x+5))]$$

e.g for  $x=5$ ,

$$R(5) = N'(5) / [(1/10) * (N'(0) + N'(1) + N'(2) + N'(3) + N'(4) + N'(6) + N'(7) + N'(8) + N'(9) + N'(10))]$$

Thus using table 3.2.1 for 1969 female data, we have:

$$R(5) = 1.008353$$

We should note that 5 is the lowest age for which an age ratio can be computed. Similarly, the age ratios for the remaining specific ages are worked out upto and including age A-6. A is the age beginning the open age interval. In our case, A=70. Table 3:1 below gives the age ratios for females and males separately and together for the 1969 data.

Step 2: The results from table 3:1 are then put in a summary form as shown in table 3:2 for computational convenience. For example, the age ratio for age 5 is entered in the cell corresponding to age group 5-9 and digit 5. This is done for the ages 5 to A-6.

TABLE 3:2: AGE RATIOS INDICATING PREFERENCE FOR SPECIFIC AGES FOR THE 1969 FEMALES

Age group	terminal digits					mean age ratio
	5/0	6/1	7/2	8/3	9/4

The last column of table 3:2 is obtained by taking the arithmetic mean of age ratios corresponding to specific age groups. This column may give an indication of age groups that gain or lose persons as a result of age heaping.

Step 3: Absolute deviations of age ratios in table 3:2 from one are entered into table 3:3 as shown below.

TABLE 3:3: ABSOLUTE DEVIATIONS OF AGE RATIOS FROM ONE - 1969 FEMALES

Age group	terminal digits				mean dev.		mean dev. from one
	5/0	6/1	7/2	8/3	9/4	from one	
5-9	.0083534	.0911500	.0784292	.1207610	.1006206	.0798628	
10-14	.1033337	.2669762	.1641560	.1415319	.0242047	.1400405	.1099517

Sum. of mean dev. from one= 1.547527

The last two columns of table 3:3 are obtained by taking the arithmetic mean of absolute deviations from one for specific age intervals. The second last column is for 5 - year age groups. while the last column is for 10 - year age intervals. These columns are useful in identifying the amount of error in each age interval. The summation of the last column, i.e sum of means of absolute deviations from one, may be used as an index of error resulting from age heaping. The higher the index, the higher the degree of age heaping.

GRAPHS OF AGE RATIO AGAINST AGE

Fig. 3.1 FEMALES 1969

Fig. 3.2 MALES 1969

GRAPHS OF AGE RATIO AGAINST AGE

Fig 3.3 FEMALE 1979

Fig 3.4 MALES 1979

The foregoing procedure is then repeated for 1969 males, 1979 females and 1979 males with the corresponding tables given in appendix D. Figures 3:1 to 3:4 give graphs of age ratios vs age.

#### 1969 FEMALES

The ages that experience greatest heaping (i.e with an age ratio of 1.2 or above) include ages 60, 50, 40, 30, 45, 20, 28, 35, 18 and 55 in that order. There is a general tendency to heap on ages ending in digits 0, 5 and 8 with an exception of age 15. The ages that are most avoided (i.e with an age ratio of 0.8 or less) are ages 31, 53, 44, 33, 41, 57, 43, 61, 64, 47, 63, 37, 23, 34, 46, 54, 51, 27 and 21 in that order. The age groups that gained persons as a result of age heaping are 60-64, 25-29, 50-54, 35-39 and 5-9 in that order. The remaining age groups, particularly age groups 30-34 and 55-59, lost part of their population. Absolute deviations of age ratios from one show that there is a considerable amount of age error arising from age heaping in the even age groups as compared to the odd age groups. Here, even age groups refer to age groups 10-14, 20-24, 30-34 and so on. The age groups 5-9, 15-19, 25-29 etc. are referred to as odd age groups. The degree of age heaping is observed to increase with age, except for the age interval 45-54 which has a greater amount of error than the 55-64 age interval.

#### 1969 MALES

The ages that experience greatest heaping are 60, 50, 40, 30, 45, 55, 35, 20, 18, 12, 48 and 38 in that order. Again, there is a tendency to heap on ages with terminal digits 0, 5 and 8 with an

exception of age 15. The ages that are most avoided are ages 53, 44, 31, 43, 41, 61, 57, 33, 64, 63, 11, 34, 51, 37, 46, 54, 59, 47 and 52 in that order. The age groups that gained population as a result of age heaping are 60-64, 45, 35-39 and 5-9 in that order. The rest of the age groups, and in particular age groups 40-44, 50-54, 20-24 and 30-34, lost part of their population to the surrounding age groups. There is a greater amount of age error in the even than the odd age groups. The degree of age heaping is observed to increase with age except for the age interval 45-54 which has a greater amount of error than the age interval 55-64.

#### 1979 FEMALES

The ages that experience greatest heaping are 60, 50, 40, 65, 30, 59, 49, 20, 69 and 45 in that order. There is a tendency to heap on ages with terminal digits 0, 5 and 9 except for ages 15, 55, 19 and 29. The ages that are most avoided are: 66, 63, 62, 64, 53, 56, 67, 33, 46, 41, 57, 52, 54, 44, 34, 42, 43, 31 and 47 in that order. The age groups that gained population as a result of age heaping are: 50-54, 65-69, 15-19 and 40-44. The remaining age groups and in particular 20-24, 60-64 and 30-34, lost part of their population to surrounding age groups. Again, the amount of error arising from age heaping is greater in the even than the odd age groups and the degree of heaping increases with age.

#### 1979 MALES

Greatest amount of heaping is observed in ages 65, 60, 40, 50, 30, 45, 59 and 20 in that order. There is heaping on all ages ending in digits 0 and 5 except for age 15. The ages that are

most avoided are ages 63, 62, 66, 64, 41, 53, 44, 34, 46, 33, 67, 11 and 56 in that order. The age group that gained population as a result of age heaping are: 65-69, 40-44, 50-54 and 10-14 in that order. The remaining age groups, particularly 60-64, 35-39 and 20-24 lost part of their population to the surrounding age groups. The degree of heaping increases with age and is greater for the even age groups than the odd age groups.

For both males and females, the considerable amount of heaping on digits 0 and 5 could be attributed to universal preference for these terminal digits. Where the respondent is ignorant of his/her age, there is a tendency to round up ages to the nearest multiple of 10 or 5. This was the case for both the 1969 and the 1979 censuses. The marked heaping on terminal digits 8 and 9 is possibly a result of assigning ages ending in these digits to those reporting a year of birth ending in digit 0, since the censuses were conducted in August 1969 and August 1979 respectively. However, the pattern of heaping on terminal digits 8 and 9 was fairly interesting. Heaping on ages ending in digit 8 was only observed in the 1969 census data and was more pronounced in the early ages of 18 and 28, whereas heaping on terminal digit 9 was only observed in the 1979 census data and was more pronounced in old ages like 49, 59 and 69. In all the cases considered, there is a general tendency for the degree of age heaping to increase with age. This could be explained in terms of: (i) Due to memory lapse, the older respondents are more likely to be ignorant of their ages, and as a result, their ages are either estimated by themselves or by the enumerator based on

external clues with the result that these ages are rounded up to the universally preferred terminal digits of 0 and 5. (ii) Lack of education or proper written records among the older respondents may also lead to rounding up of ages to terminal digits 0 or 5. The greater amount of error in the even age groups than the odd age groups is possibly due to greater heaping on terminal digit 0 than terminal digits 5, 8 or 9. The degree of heaping was observed to be greater for females than males possibly due to better education and better written records for males. Similar reasons may be used to explain why the degree of heaping was greater in the 1969 census than the 1979 census.

### 3.3 THE AGE SPECIFIC GROWTH RATE TECHNIQUE

#### 3.3.1: THE THEORY

The age specific growth rate technique is an extension of the stable population theory by making the growth rate a function of age. Apart from being useful in the estimation of the degree of completeness of death registration, construction of life tables, estimation of adult mortality from data on orphanhood, estimation of mean age at marriage, estimation of fertility measures and net migration rates, finding out the relative coverage of censuses and making population projections, the age specific growth rate technique can also be used to detect age misreporting as will be shown in this section.

Let  $N(x)$  = the number of persons aged  $x$

$u(x)$  = the age specific mortality rate at exact age  $x$

$r$  = the constant growth rate.

In a stable population,

$$N(x) = N(0).p(x) \exp(-rx) \quad (3.3.1)$$

Where  $p(x)$  is the probability of surviving upto age  $x$  from birth.

Differentiating (1) with respect to  $x$ , we get:

$$\frac{dN}{dx} = N(x) \left[ -r + \frac{d}{dx} \log P(x) \right] \quad (3.3.2)$$

But by definition,

$$\begin{aligned} u(x) &= - \frac{1}{l(x)} \frac{dl}{dx} \\ &= - \frac{1}{dx} \log p(x) \end{aligned} \quad (3.3.3)$$

Therefore equation (3.3.2) becomes:

$$\frac{1}{N(x)} \frac{dN}{dx} = -r - u(x) \quad (3.3.4)$$

Thus the relative change in the number of persons at age  $x$  diminishes at a rate of  $r + u(x)$ .

Suppose now that the rate of increase is no longer a constant, but rather a function of age, then equation (3.3.4) can be modified to:

$$\frac{1}{N(x)} \frac{dN}{dx} = -r(x) - u(x)$$

$$\text{i.e. } \frac{d}{dx} \log N(x) = -r(x) - u(x) \quad (3.3.5)$$

If  $a < x < a+n$ , then integrating (3.3.5), we have:

$$N(a+n) = N(a) \cdot nPa \cdot \exp \left[ - \int_a^{a+n} r(x) dx \right] \quad (3.3.6)$$

$$\text{where } nPa = \exp \left[ - \int_a^{a+n} u(x) dx \right] \quad (3.3.7)$$

If  $0 < x < a$ , then we have:

$$N(a) = N(0) p(a) \exp \left[ - \int_0^a r(x) dx \right] \quad (3.3.8)$$

where  $p(a) = \exp \left[ - \int_0^a u(x) dx \right]$  (3.3.9)

is the probability of surviving from birth upto age a.

The birth rate is expressed as:

$$\begin{aligned}
 b &= \frac{N(0)}{\int_0^{\infty} N(a) da} \\
 &= \frac{1}{p(a) \left\{ \exp \left[ - \int_0^{\infty} r(x) dx \right] \right\} da} \quad (3.3.10)
 \end{aligned}$$

using formular (3.3.8).

The proportion of the population that is aged a is given by:

$$\begin{aligned}
 C(a) &= \frac{N(a)}{\int_0^{\infty} N(a) da} \\
 &= bp(a) \exp \left[ - \int_0^a r(x) dx \right] \quad (3.3.11)
 \end{aligned}$$

The proportion of people aged between x and x+5 years is given by:

$$\begin{aligned}
 5C_x &= \int_x^{x+5} C(a) da \\
 &= \int_x^{x+5} bp(a) \left[ \exp \left[ - \int_0^a r(y) dy \right] \right] da \quad (3.3.12)
 \end{aligned}$$

The mid - point of x and x+5 is x+2.5. Thus, we can replace

$$\int_0^a r(y) dy \text{ by } \int_0^{x+2.5} r(y) dy.$$

Therefore,

$$\begin{aligned}
 5C_x &= \int_x^{x+5} bp(a) \left\{ \exp \left[ - \int_0^{x+2.5} r(y) dy \right] \right\} da. \\
 &= \left\{ b \exp \left[ - \int_0^{x+2.5} r(y) dy \right] \right\} \left\{ \int_x^{x+5} p(a) da \right\}
 \end{aligned}$$

0

x

$$= \left\{ b \exp \left[ - \int_0^{x+2.5} r(y) dy \right] \right\} \frac{5Lx}{l(0)} \quad (3.3.13)$$

$$\text{where } 5Lx = \frac{x+5}{x} l(a) da \quad (3.3.14a)$$

$$\text{and } p(a) = \frac{l(a)}{l(0)} \quad (3.3.14b)$$

$5Lx$  is called the person - years lived between ages  $x$  and  $x+5$ .

But,

$$\begin{aligned} \int_0^{x+2.5} r(y) dy &= \int_0^5 r(y) dy + \int_5^{10} r(y) dy + \dots + \int_{x-5}^x r(y) dy + \int_x^{x+2.5} r(y) dy \\ &= 5[5r_0 + 5r_5 + \dots + 5r_{(x-5)}] + 2.5[5r_x] \quad (3.3.15) \end{aligned}$$

where  $5r_x$  is the age specific growth rate between ages  $x$  and  $x+5$ .

Assuming constant growth rates within the five - year age interval;

$$5C_x = b \frac{5Lx}{l(0)} \exp \{ -5[5r_0 + 5r_5 + \dots + 5r_{x-5}] + 2.5(5r_x) \} \quad (3.3.16)$$

$$\text{and } 5C_0 = b \frac{5L_0}{l(0)} \exp \{ -2.5[5r_0] \} \quad (3.3.17)$$

To determine  $b$ , we sum (3.3.13) over  $x$  and noting that

$$\sum_{x=0}^w 5C_x = 1$$

we obtain

$$b = \frac{1}{\sum_{x=0}^w \frac{5Lx}{l(0)} \exp \left[ - \int_0^{x+2.5} r(y) dy \right]} \quad (3.3.18a)$$

$$= \frac{1}{\sum_{x=0}^{\omega} \frac{5Lx}{1(0)} \exp \{-5[5r_0 + 5r_5 + \dots + 5r_x - 5] - 2.5(5rx)\}} \quad (3.3.18b)$$

Therefore,

$$5C_0 = \frac{5L_0 \exp [-2.5 (5r_0)]}{\sum_{x=0}^{\omega} 5Lx \exp \left[-\int_0^{x+2.5} r(y) dy\right]} \quad (3.3.19a)$$

$$= \frac{5L_0 \exp [-2.5(5r_0)]}{\sum_{x=0}^{\omega} 5Lx \exp \{-5[5r_0 + 5r_5 + \dots + 5r_x - 5] - 2.5(5rx)\}} \quad (3.3.19b)$$

$$5C_x = \frac{5Lx \exp \left[-\int_0^{x+2.5} r(y) dy\right]}{\sum_{x=0}^{\omega} 5Lx \exp \left[-\int_x^{x+2.5} r(y) dy\right]} \quad (3.3.20a)$$

$$= \frac{5Lx \exp \{-5[5r_0 + 5r_5 + \dots + 5r_x - 5] - 2.5(5rx)\}}{\sum_{x=0}^{\omega} 5Lx \exp \{-5[5r_0 + 5r_5 + \dots + 5r_x - 5] - 2.5(5rx)\}} \quad (3.3.20b)$$

From formulae (3.3.19b) and (3.3.20b), we have:

$$\begin{aligned} \frac{5C_x}{5C_0} &= \frac{5Lx \exp \{-5[5r_0 + 5r_5 + \dots + 5r_x - 5] - 2.5(5rx)\}}{5L_0 \exp \{-2.5(5r_0)\}} \\ &= \frac{5Lx}{5L_0} \exp \{-2.5(5r_0) + 5(5r_5 + \dots + 5r_x - 5) + 2.5(5rx)\} \end{aligned}$$

Which implies that

$$\frac{5Lx}{5L_0} = \frac{5C_x}{5C_0} \exp \{2.5(5r_0) + 5(5r_5 + \dots + 5r_x - 5) + 2.5(5rx)\} \quad (3.3.21)$$

For the open interval, say age A and over, we have:

$$C(A+) = b \frac{T(A)}{l(0)} \exp \{-5[5r_0+5r_5+\dots+5r_{A-5}] - (2/3)e(A).r(A+)\} \quad (3.3.22a)$$

$$= \frac{T(A) \exp \{-5[5r_0+5r_5+\dots+5r_{A-5}] - (2/3)e(A).r(A+)\}}{\sum_{x=0}^{\omega} 5Lx \exp \{-5[5r_0+5r_5+\dots+5r_{x-5}] - 2.5(5rx)\}} \quad (3.3.22b)$$

where  $e(A)$  = Expectation of life at age A

$r(A+)$  = The growth rate for age A and above

$T(A)$  = The total population for those aged A and over

$$= \int_A^{\omega} l(x) dx$$

From two censuses, the growth rates,  $5rx$ , can be calculated by simply applying the formula:

$$5rx = \frac{1}{t_2 - t_1} \log \left[ \frac{5N_x(t_2)}{5N_x(t_1)} \right] \quad (3.3.23)$$

where  $t_1$  and  $t_2$  are the periods the censuses were taken.

Using (3.3.22b) and (3.3.17), we have:

$$\frac{T(A)}{5L_0} = \frac{C(A+)}{5C_0} \exp \{2.5(5r_0)+5(5r_5+\dots+5r_{A-5}) + (2/3)e(A).r(A+)\} \quad (3.3.24)$$

Once we have obtained a column of  $5Lx/5L_0$ , it is now a matter of adding these values from down upwards to get  $T(x)/5L_0$ .

$$\text{Hence, } \frac{T(x)}{T(5)} = \left[ \frac{T(x)}{5L_0} \right] / \left[ \frac{T(5)}{5L_0} \right] \quad (3.3.25)$$

From the Office of Population Research, Princeton University, computerized tables of  $T(x)/T(5)$  against mortality levels have been made for each region (i.e East, West, North and South) and sex. We should note that the tables of  $T(x)/T(5)$  are computed from  $T(x)$  values

for each mortality level of the Coale - Demeny model life tables.

A graph of age against mortality levels is then plotted. It is hypothesized that if the graph is rising, then there is an indication of overstatement of age. A graph showing a downward trend implies under-estimation of age. A horizontal graph implies correct age statement.

3.3.2 APPLICATION OF THE AGE SPECIFIC GROWTH RATE TECHNIQUE TO KENYA'S DATA

Step 1: The 1969 and the 1979 female populations, denoted by  $5N_1(x)$  and  $5N_2(x)$  respectively are entered into columns (1) and (2) of table 3:4, and the geometric mean of the 1969 and 1979 populations,  $5N'(x)$ , is entered into column (3).

i.e  $5N'(x) = \text{SQRT} [5N_1(x) * 5N_2(x)]$

e.g for  $x = 0$ ,

$5N'(0) = \text{SQRT} [1046380 * 1423936] = 1220646$ : for Kenyan females

Step 2: The proportion of the population aged  $x$  to  $x+4$  years,  $5C(x)$ , is obtained by dividing the values in column (3) by the total sum of column (3).

i.e  $5C(x) = \frac{5N'(x)}{\sum_{x=0}^{\infty} 5N'(x)}$

$\sum_{x=0}^{\infty} 5N'(x)$

e.g for  $x = 0$ ,

$5C(0) = 1220646 / 6487234 = 0.188161$

These values are entered into column (4) of table 3:4.

Step 3: The age specific growth rates,  $5r_x$ , are obtained from formula (3.3.23).

i.e  $5r_x = 1/10 \log [5N_2(x)/5N_1(x)]$

e.g for  $x = 0$ ,

$$5r_0 = 1/10 \log [1423936/1046380] = 0.030808.$$

These values are entered into column (5). The sum of  $5r_x$  values, starting from  $x = 5$ , are given in column (6).

Step 4: The  $5C_x/5C_0$  values in column (7) are obtained by dividing column (4) with  $5C_0 = 0.188161$ .

e.g for  $x = 5$ ,

$$5C_0/5C_5 = 0.162698/0.188161 = 0.864675.$$

TABLE 3:4: DETECTING AGE MISREPORTING FOR KENYAN FEMALES - ASGR7

5460324 7719947 6487235.

Step 5: The  $5L_x/5L_0$  values in column (1) of table 3:5 are obtained from formula (3.3.22).

$$i.e \quad \frac{5L_x}{5L_0} = \frac{5C_x}{5C_0} \exp \{2.5(5r_0) + 5(5r_5 + \dots + 5r_{x-5}) + 2.5(5r_x)\}$$

where  $5L_x$  is the person years lived by those aged  $x$  to  $x+4$  year

e.g for  $x = 5$ ,

$$\frac{5L_x}{5L_0} = \frac{5C_5}{5C_0} \exp \{2.5(5r_0) + 0 + 2.5(5r_5)\}$$

$$\begin{aligned} &= 0.864675 \exp \{2.5(0.030808)+2.5(0.033347)\} \\ &= 1.015107 \end{aligned}$$

Step 6: The  $T(x)/5L0$  values in column (2) are obtained by cumulating column (1) from down.

$$\text{i.e. } \frac{T(x)}{5L0} = \sum_{y=x} 5Ly$$

where  $T_x$  is the person years lived by those aged  $x$  years and above, and  $w$  is the latest age to which one can survive.

e.g for  $x=5$ ,

$$\frac{T(5)}{5L0} = \sum_{y=5} 5Ly = 11.79196$$

Step 7: The  $T(x)/T(5)$  values in column (3) are obtained by dividing column (2) by  $T(5)/5L0 = 11.79196$ , as shown in formular (3.3.25)

$$\text{i.e. } T(x)/T(5) = [T(x)/5L0] / [T(5)/5L0].$$

e.g for  $x = 10$ ,

$$T(10)/T(5) = 10.77685/11.79196 = 0.913915$$

Assuming  $e(70) = 7.612$

DETECTING AGE MISREPORTING : THE ASGR TECHNIQUE .

Fig 3:5 FEMALES

Fig 3:6 MALES

A graph of age against mortality level is then plotted as shown in figure 3:5 for Kenyan females.

The same procedure has been followed for the case of Kenyan males with corresponding tables given in appendix E, along with figure 3:6.

#### AGE REPORTING AMONG THE FEMALES

There is considerable overstatement of age among the teenagers and those aged 45-49, 50-54, 60-64 and 65-69 while the age groups 35-39, 40-44 and 55-59 only show mild over-reporting of age. Over-reporting of age among the teenagers could be attributed to the fact that most adolescents would like to appear older than they actually are, particularly those who are faster than usual in maturing physically. Furthermore, teenagers who are married or have at least a child would tend to over-report their ages so as to be seen as adults. Old people are generally respected in a society and this fact may explain why there is a general tendency to over-report age among those aged 35 years and above. On the other hand, young women aged between 20 to 34 years, and particularly those who are unmarried, will tend to under-report their ages so as to appear younger than they actually are.

#### AGE REPORTING AMONG THE MALES

For males, there is a tendency to over-report age throughout the age distribution, and in particular, among those in their late twenties and above age 40 years. Generally, men are considered mature and capable of taking care of a family responsibly when they are around 30 years old. For this reason, married men in

their late twenties may tend to over-state their ages to appear older. Again, age exaggeration among those aged 40 years and above could be attributed to the respect the society - attached to the elderly.

## CHAPTER 4

### CORRECTION OF AGE ERRORS

#### 4.2. INTRODUCTION

In this chapter, an attempt is made to estimate Kenya's age distribution by correcting for the age misreporting errors. The Demeny - Shorter method is used to detect and correct systematic age misreporting, where as the Saxena - Gogte technique is used to correct for heaping on multiples of five. The two methods are first applied separately, then jointly to Kenya's data. Following the correction of age errors, the efficiency or appropriateness of the correction techniques to Kenyan data is examined by studying the correspondence between the techniques of detecting and of correcting age errors. This will help to identify the method that gives the best estimate of Kenya's age distribution. Finally, the extent to which some of the assumptions made in the study with regard to changes in census coverage, mortality level and life expectancy at old age could have affected the results is examined.

#### 2 THE DEMENY - SHORTER METHOD

##### 2.1 THE THEORY

The Demeny - Shorter method is a cohort survival method of correcting age distributions. It is based on the following assumptions: first, that the pattern of age misreporting is systematic and therefore repeats itself from one census to the next; second, that the population can be assumed to experience

mortality according to an appropriately selected model mortality schedule; and third, that the total size of the population was enumerated correctly or at least that the coverage of the two censuses are reasonably close.

The method can be represented mathematically using the following notations:

Let  $i = 1, 2, \dots, 16$  represent the  $i$ th age group. The

The 16 age groups are 0-4, 5-9, ..., 70-74, 75+.

$P_i$  = The known reported populations in age group  $i$  in the first census.

$Q_i$  = The known reported population in age group  $i$  in the second census.

$C_i$  = The unknown actual population in age group  $i$  in the first census.

$D_i$  = The unknown actual population in age group  $i$  in the second census.

$S_i$  = The known survivorship rate from age group  $i$  to  $i+1$

(For  $i=15$  and  $i=16$ ,  $S(15)$  is the rate from 70-74 to 75-79, and  $S(16)$  is the rate from 75+ to 80+.

$e_i$  = The unknown ratio of reported to actual population in age group  $i$ .

We note that in terms of  $nL_x$ , the life table stationary population column,

$$S_i = 5L5i / 5L5(i-1), \quad i = 1, \dots, 15.$$

$$S_{16} = L80 / L75.$$

From the above assumptions, we can formulate the following equations:

$$\text{and } P_i = e_i C_i \quad \text{for } i = 1, 2, \dots, 16 \quad (4.2.1a)$$

$$Q_i = e_i D_i \quad \text{for } i = 1, 2, \dots, 16 \quad (4.2.1b)$$

$$D(i+1) = S_i C_i \quad \text{for } i = 1, 2, \dots, 14. \quad (4.2.2a)$$

and 
$$D(16) = S(15)C(15) + S(16)C(16) \quad (4.2.2b)$$

$$\sum_{i=1}^{16} P_i = \sum_{i=1}^{16} C_i \quad (4.2.3a)$$

and 
$$\sum_{i=1}^{16} Q_i = \sum_{i=1}^{16} D_i \quad (4.2.3b)$$

general, the last (open) age groups could be represented by L. In is case L = 16. It can be seen from the above sets of equations in (4.2.1), (4.2.2) and (4.2.3) that we have 48 unknown parameters (i.e C<sub>i</sub>'s, 16 D<sub>i</sub>'s and 16 e<sub>i</sub>'s) and 49 independent equations.

From (4.2.1b),

$$Q_i = e_i D_i \quad ==> \quad Q(i+1) = e(i+1)D(i+1).$$

Thus, 
$$e(i+1) = \frac{Q(i+1)}{D(i+1)}, \quad \text{for all } i.$$

Using (4.4.2),

$$e(i+1) = \frac{Q(i+1)}{S_i C_i}, \quad \text{for } i = 1, 2, \dots, 14 \quad (4.2.4a)$$

and 
$$e(16) = \frac{Q(16)}{D(16)} = \frac{Q(16)}{S(15)C(15) + S(16)C(16)}, \quad \text{for } i = 15. \quad (4.2.4b)$$

$$==> \quad Q(16) = e(16)S(15)C(15) + e(16)S(16)C(16)$$

$$==> \quad C(15) = \frac{Q(16) - S(16)P(16)}{e(16)S(15)} \quad (4.2.5)$$

$$==> \quad C(15)e(16) = \frac{Q(16) - S(16)P(16)}{S(15)}$$

From (4.2.1a),

$$e(1)C(1) = P(1) \tag{4.2.6a}$$

$$\text{and } e(1)C(1)e(2)C(2)\dots\dots\dots e(i-1)C(i-1)e_i C_i = P(1)P(2)\dots\dots P_i$$

which implies that:

$$e(1)C_i = \frac{P(1)P(2)\dots\dots\dots P_i}{C(1)e(2)C(2)e(3)\dots\dots C(i-1)e_i}, \quad \text{for } i = 2, \dots, 15$$

but from (4.2.4),

$$C(i)e(i+1) = \frac{Q(i+1)}{S_i}, \quad \text{for } i = 1, 2, \dots, 14$$

i.e  $C(1)e(2) = Q(2)/S(1)$ ,  $C(2)e(3) = Q(3)/S(2)$  and so on.

Therefore:

$$\begin{aligned} e(1)C(i) &= \frac{P(1)P(2)\dots\dots\dots P(i)}{Q(2)/S(1) \ Q(3)/S(2)\dots\dots Q(i)/S(i-1)} \\ &= \frac{P(1)P(2)\dots\dots P(i)S(1)S(2)\dots\dots S(i-1)}{Q(2)Q(3)\dots\dots Q(i)}, \tag{4.2.6b} \\ &\quad \text{for } i = 2, 3, \dots, 15 \end{aligned}$$

Now consider,

$$e(1)C(1)e(2)C(2)\dots\dots\dots e(16)C(16) = P(1)P(2)\dots\dots\dots P(16)$$

$$\begin{aligned} \Rightarrow e(1)C(1) &= \frac{P(1)P(2)\dots\dots\dots P(16)}{C(1)e(2)C(2)e(3)\dots\dots\dots C(15)e(16)} \\ &= \frac{P(1)P(2)\dots\dots\dots P(16)}{Q(2)/S(1) \ Q(3)/S(2)\dots\dots\dots Q(15)/S(14) \ C(15)e(16)} \end{aligned}$$

From (4.2.5),

$$C(15) = \frac{Q(16) - S(16)P(16)}{e(16)S(15)}$$

$$\Rightarrow C(15)e(16) = \frac{Q(16) - S(16)P(16)}{S(15)}$$

$$\begin{aligned} \Rightarrow e(1)C(16) &= \frac{P(1)P(2)\dots\dots\dots P(16)}{\frac{Q(2)}{S(1)} \frac{Q(3)}{S(2)} \dots\dots\dots \frac{Q(15)}{S(14)} \left[ \frac{Q(16) - S(16)P(16)}{S(15)} \right]} \\ &= \frac{P(1)P(2)\dots\dots\dots P(16)S(1)S(2)\dots\dots\dots S(15)}{Q(2)Q(3)\dots\dots\dots Q(15)[Q(16) - S(16)P(16)]} \end{aligned} \quad (4.2.6c)$$

Summing up both sides of the equations (4.2.6a) to (4.2.6c), we get:

$$\begin{aligned} e(1) \sum_{i=1}^{16} C_i &= e(1)C(1) + \sum_{i=2}^{15} e(1)C(i) + e(1)C(16) \\ &= P(1) + \sum_{i=2}^{15} \frac{P(1)P(2)\dots\dots\dots P(i)S(1)S(2)\dots\dots\dots S(i-1)}{Q(2)Q(3)\dots\dots\dots Q(i)} \\ &\quad + \frac{P(1)P(2)\dots\dots\dots P(16)S(1)S(2)\dots\dots\dots S(15)}{Q(2)Q(3)\dots\dots\dots Q(15)[Q(16) - S(16)P(16)]} \\ e(1) &= \frac{1}{\sum_{i=1}^{16} P(i)} \left[ P(1) + \sum_{i=2}^{15} \frac{P(1)P(2)\dots\dots\dots P(i)S(1)S(2)\dots\dots\dots S(i-1)}{Q(2)Q(3)\dots\dots\dots Q(i)} \right. \\ &\quad \left. + \frac{P(1)P(2)\dots\dots\dots P(16)S(1)S(2)\dots\dots\dots S(15)}{Q(2)Q(3)\dots\dots\dots Q(15)[Q(16) - S(16)P(16)]} \right] \end{aligned} \quad (4.2.7)$$

With this value of e(1) in equation (4.2.7) we can calculate C's from equations (4.2.6) and then D's and other e's from equations (4.2.1).

Alternatively, we can eliminate equation (4.2.3b) to solve the 48 knowns.

Given:  $e_i D_i = Q_i$ ,  
for all i

$e_i C_i = P_i$ ,

and  $S_i C_i = D(i+1)$ , for  $i=1,2,\dots,14$

Multiplying (4.2.1a) by  $S_i$ , we have:

$$e_i C_i S_i = P_i S_i \implies e_i D(i+1) = P_i S_i \quad (4.2.8)$$

From (4.2.1b),  $e_1 D_1 = Q_1 \quad (4.2.9a)$

From (4.2.8),  $e_1 D_2 = P_1 S_1 \quad (4.2.9b)$

Further,

$$e(1)D(2)e(2)D(3) = P(1)S(1)P(2)S(2)$$

$$\implies e(1)Q(2)D(3) = P(1)P(2)S(1)S(2)$$

$$\implies e(1)D(3) = [P(1)P(2)S(1)S(2)]/Q(2)$$

Thus,  $e(1)D(2)e(2)D(3)e(3)D(4) = P(1)S(1)P(2)S(2)P(3)S(3)$

$$\implies e(1)Q(2)Q(3)D(4) = P(1)P(2)P(3)S(1)S(2)S(3)$$

$$\implies e(1)D(4) = [P(1)P(2)P(3)S(1)S(2)S(3)]/[Q(2)Q(3)]$$

general,

$$e(1)D(2)e(2)D(3)\dots e(i-1)D(i) = P(1)S(1)P(2)S(2)\dots (i-1)S(i-1)$$

$$\text{for } i = 2, 3, \dots, 15$$

$$e(1)Q(2)Q(3)\dots Q(i-1)D(i) = P(1)P(2)\dots P(i-1)S(1)S(2)\dots S(i-1)$$

$$\implies e(1)D(i) = \frac{P(1)P(2)\dots P(i-1)S(1)S(2)\dots S(i-1)}{Q(2)Q(3)\dots Q(i-1)} \quad (4.2.9c)$$

Now consider,

$$e(16) = \frac{Q(16)}{D(16)} = \frac{Q(16)}{S(15)C(15) + S(16)C(16)}$$

$$\implies Q(16) = e(16)S(15)C(15) + e(16)S(16)C(16)$$

$$\implies C(15) = [Q(16) - S(16)P(16)]/[e(16)S(15)]$$

Therefore,

$$e(15) = P(15)/C(15) = [P(15)e(16)S(15)]/[Q(16) - S(16)P(16)]$$

Multiplying both sides by  $D(16)$ , we have:

$$e(15)D(16) = \frac{P(15)e(16)S(15)D(16)}{Q(16) - S(16)P(16)} \quad \text{but } D(16) = \frac{Q(16)}{e(16)}$$

$$\Rightarrow e(15)D(16) = \frac{P(15)e(16)S(15)[Q(16)/e(16)]}{Q(16) - S(16)P(16)} = \frac{P(15)S(15)Q(16)}{Q(16) - S(16)P(16)}$$

Therefore,

$$e(1)D(2)e(2)D(3)\dots\dots e(14)D(15)e(15)D(16)$$

$$= P(1)P(2)\dots P(14)S(1)S(2)\dots S(14)\left[\frac{P(15)S(15)Q(16)}{Q(16) - S(16)P(16)}\right]$$

$$\Rightarrow e(1)Q(2)Q(3)\dots Q(15)D(16) = \frac{P(1)P(2)\dots P(15)S(1)S(2)\dots S(15)Q(16)}{Q(16) - S(16)P(16)}$$

$$\Rightarrow e(1)D(16) = \frac{P(1)P(2)\dots P(15)S(1)S(2)\dots S(15)Q(16)}{[Q(2)Q(3)\dots Q(15)][Q(16) - S(16)P(16)]} \quad (4.2.9d)$$

Summing up both sides of the equations in (4.4.9), we have:

$$(1) \sum_{i=1}^{16} D(i) = e(1)D(1) + e(1)D(2) + \sum_{i=3}^{15} e(1)D(i) + e(1)D(16)$$

$$= Q(1) + P(1)S(1) + \sum_{i=3}^{15} \frac{P(1)P(2)\dots P(i-1)S(1)S(2)\dots S(i-1)}{Q(2)Q(3)\dots Q(i-1)}$$

$$+ \frac{P(1)P(2)\dots P(15)S(1)S(2)\dots S(15)Q(16)}{Q(2)Q(3)\dots Q(15)[Q(16) - S(16)P(16)]}$$

Therefore,

$$e(1) = \frac{1}{\sum_{i=1}^{16} Q(i)} [Q(1) + P(1)S(1) + \sum_{i=2}^{14} \frac{P(1)P(2)\dots P(15)S(1)S(2)\dots S(15)Q(16)}{Q(2)Q(3)\dots Q(i)} + \frac{P(1)P(2)\dots P(15)S(1)S(2)\dots S(15)Q(16)}{Q(2)Q(3)\dots Q(15)[Q(16) - S(16)P(16)]}] \quad (4.2.10)$$

With this value of e(1) in equation (4.2.10), we can calculate D's from equations (4.2.9) and then C's and remaining e's from equations (4.2.1). a practical solution, the average of the two ratios is taken as the best estimate.

2.2: APPLICATION OF THE DEMENY - SHORTER METHOD TO KENYA'S DATA

since the censuses used in this study are ten and not five years apart, and we intend to obtain correction factors for five year age groups, the 1974 population has been estimated as the geometric mean of the 1969 and the 1979 populations to enable us work with sets of population data separated by five years. The survival ratios for mortality level 14.10164 - females, North model are worked out by linear interpolation.

for this application, let

$P_i = 5N_1(x)$  be the enumerated 1969 population,

$Q_i = 5N_2(x)$  be the enumerated 1979 population,

$C_i = 5N_1^*(x)$  be the corrected 1969 population,

$D_i = 5N_2^*(x)$  be the corrected 1979 population and

$5N'(x)$  be the estimated 1974 population.

TABLE 4:1:THE 1969, 1974 AND 1979 FEMALE POPULATIONS AND THE SURVIVAL RATIOS FOR LEVEL 14.10164 - FEMALES, NORTH MODEL

age, x	POPULATIONS			SURVIVAL RATIOS		
	$5N_1(x)$ (1)	$5N_2(x)$ (2)	$5N'(x)$ (3)	LEVEL 14 (4)	LEVEL 15 (5)	*LEVEL* (6)

LEVEL\* - Mortality level 14.10164- Females, North model (Mudaki, 1986)

Step 1: obtaining correction factors for 1969 and 1974.

The 1969 and the 1979 census populations are corrected as follows:

(a) The enumerated 1969 and estimated 1974 populations are entered into columns (1) and (2) as shown in table 4.2. for Kenyan females. (b) A mortality level is selected. In this application, the levels come from the analysis by Mudaki (1986). The schedule of cohort survivorship rates comes from the appropriate model (i.e level 14.10164, North model for females and level 14.34975, North model for males). and is entered into column (3). (c) A provisional set of correction factors is calculated on the basis of a provisional assumption, which is dropped later, that the age group 0-4 was enumerated correctly. The selection of the age group 0-4 is purely a computational convenience which does not affect the final results. The 0-4 age group correction factor is written in column (4) as 1.0000 and the enumerated populations entered as corrected populations in columns (5) and (6).

(d) The enumerated population of the 0-4 age group in the 1969 census is multiplied by the survivorship rate for this age group.

The answer is the corrected population for the 5-9 age group at the date of the second census. This is given in column (6)

$$\text{e.g } 1046380 * 0.940030 = 983629.1$$

(e) The ratio which the corrected population for the 5-9 age group bears to the enumerated population is calculated. This gives the correction factor for the 5-9 age group and is entered into column (4) e.g  $983629.1/1055463 = 0.93194$

(f) The enumerated population at the first census date is

multiplied by the correction factor. The result is the corrected population for the 5-9 age group in the first census.

$$\text{e.g } 893359 * 0.93194 = 832557.2$$

(g) This procedure is repeated for each succeeding age interval until the last and open ended interval is reached. For this interval, let  $C_1$  and  $C_2$  be the enumerated populations respectively, and star the symbols for the corrected estimates. Since the ratios of the errors to the enumerated populations is assumed to be the same at both census dates,  $C_1^* = C_1/C_2 \cdot C_2^*$ , since the proportions surviving to the last age interval includes both the cohort entering from the interval below and the survivors who are already in the interval. Thus,  $C_2^* = a + (p + C_1^*)$  where  $a$  is the survivors from the next lower age interval calculated as in the previous steps, and  $p$  is the proportion surviving from within the open - ended interval to higher ages. The two equations are solved simultaneously. The correction factor for the 70+ is the ratio  $C_2^*/C_2 = C_1^*/C_1$ .

(h) Because it was assumed provisionally that the 0-4 age group was enumerated correctly, where as this age group is typically under -reported relative to the rest of the age distribution, the provisional correction factors do not produce the correct total size of the population. The error in each correction factor and in the total population is the proportion to the reporting error for the 0-4 age group. Hence, the assumed correctness of that group is dropped and it is assumed instead that the total population was enumerated correctly.

All the correction factors are then raised by a multiplier which is found by taking the ratios of the totals in columns (1) and (5) and columns (2) and (6) and comparing the results. A trivial difference between the two ratios may arise when the age distributions at the two censuses are different. As a practical solution, an average of the two ratios is used as a multiplier to produce column (7) from column (4).

6487235. 7719947

6006672. 7137107.

The ratio of enumerated to corrected totals is 1.080834

Step 3: obtaining correction factors for 1969 and 1979

The average of the correction factors in columns (7) of tables 4:2 and 4:3 (i.e for the periods 1969-74 and 1974-79 respectively) gives the correction factors for the 1969-79 period. The enumerated 1969 and 1979 populations are then multiplied by these correction factors,  $e_i$ 's to obtain the corrected 1969 and 1979 female populations as shown in table 4:4 below. A control chart for the correction factors is given in figure 4:1 for Kenyan females.

The same procedure has been followed for the case of Kenyan males with the corresponding tables given in appendix F as well as table 4.5 given below. The corresponding figures 4:1 and 4:2 for the females and the males are given below.

CONTROL CHARTS FOR CORRECTION FACTORS OBTAINED BY THE DSM

70+	131472	154453	.782138	102829.2	120803.6
TOTAL	5483281	7607185		5487018.	7607405.

Note: It is important to note that it is those age groups with

correction factors greater than one that lose population, whereas those age groups with correction factors less than one gain populations as a result of age misreporting. For this analysis, age groups with correction factors equal to  $1 + 0.025$  are considered to be fairly accurately reported.

#### AGE REPORTING FOR FEMALES

The age groups that suffer deficits are: 0-4, 40-44, 45-59, 55-59, 60-64 and 65-69, whereas age groups 15-19, 20-24, 25-29 and 70+ are over - reported. The age group 0-4 is normally under - reported due to omissions. This is so because in certain societies, children are not considered full members of the society and some, particularly those absent from home, might not be included in the enumeration exercise. At older ages, that is; age 40 onwards, it appears that systematic over - reporting of age carries people across age group boundaries to the next higher age groups and this finally leads to the age group 70+ being considerably over - reported. This could be attributed to the fact that the society gives respect to the elderly and thus the desire for most people above age 40 to appear older. The excess in the age group 15-19 is mainly as a result of this age group gaining persons from the age group 10-14. Girls in the age group 10-14 who are past menarche have a tendency to over - state their ages so as to appear older and this carries some to the 15-19 age group. The age groups 20-24 and 25-29 possibly gain persons from the older age groups due to the desire for most young women to appear younger than they actually are.

## AGE REPORTING FOR MALES

The age groups that are under - reported include: 0-4, 35-39, 40-44, 45-49, 50-54, 55-59 and 60-64, where as age groups 5-9, 10-14, 15-19, 65-69 and 70+ are over - reported. The deficit in the age group 0-4 could be as a result of omissions of young children as well as over - reporting of age among those under five so as to be included in the school going age. This consequently leads to over - reporting of the 5-9 age group. The excess in the age group 15-19 is possibly as a result of young men in the age group 20-24, who are later than usual in maturing physically, under - reporting their ages and thus falling in the 15-19 age group. Again, it appears that systematic over - reporting of age occurs above age 35 years and this carries people to next higher age groups, finally leading to considerable excesses in the 65-69 and 70+ age groups.

### 4.3 THE SAXENA - GOGTE TECHNIQUE

#### 4.3.1: THE THEORY

Age distributions obtained from censuses and surveys in most developing countries exhibit heaping on ages that are multiples of five. Feeney (1979) suggested a technique for re-distributing the excess persons at these ages to the surrounding ages. Feeney's procedure involves the transfer of excess persons from a given multiple of five to the eight immediately surrounding ages, the four years on either side of the multiple of five, in such a way that: (i) The adjusted numbers in the surrounding ages are

proportional to the original numbers; and (ii) The adjusted numbers at the lower four ages, the central age and the upper four ages form a linear progression.

Feeney's method, which involves an iterative procedure, is somewhat complicated. Saxena and Gogte (1985) showed that a simpler procedure, the nine - point moving average, yields equally effective results as the Feeney's method.

#### FEENEY'S METHOD

Let  $N(x)$  = number of persons aged  $x$  in completed years.

$N(x-)$  = number of persons aged  $x-4$  to  $x-1$  years.

$N(x+)$  = number of persons aged  $x+1$  to  $x+4$  years

Where  $x$  is a multiple of five. that is; 5, 10, 15.....

The first of the two requirements mentioned earlier: that the surrounding ages must be proportional to the existing numbers can be expressed mathematically as follows:

$$N'(x-) = N(x-) * D(x) \quad (4.3.1)$$

$$N'(x+) = N(x+) * D(x) \quad (4.3.2)$$

where primes (') indicate adjusted quantities. The constant of proportionality,  $D(x)$ , is assumed to be the same in both (4.3.1) and (4.3.2), so that the adjustments to the ages on either side of the multiple of five are multiplicatively symmetrical.

The second of the two requirements mentioned earlier: that the adjusted numbers at the lower four ages must form a linear progression, can be expressed mathematically as:

$$N'(x) = 1/2[(1/4)N'(x-) + (1/4)N'(x+)] \quad (4.3.3)$$

In other words, for the progression to be linear, the middle value must be midway between the average number of persons at the lower four ages.

Substituting (4.3.1) and (4.3.2) into (4.3.3),

we get:

$$N'(x) = 1/8D(x)[N(x-) + N(x+)] \tag{4.3.4}$$

Equations (4.3.1), (4.3.2) and (4.3.4) are valid for any value of  $Dx$ .

Suppose we define  $Dx$  as:

$$Dx = 8/9 \frac{N(x-) + N(x) + N(x+)}{N(x-) + N(x+)} \tag{4.3.5}$$

Then equations (4.3.1), (4.3.2) and (4.3.4) can be re written as:

$$N'(x-) = N(x-) + (Dx - 1)N(x-) \tag{4.3.6}$$

$$N'(x+) = N(x+) + (Dx - 1)N(x+) \tag{4.3.7}$$

$$N'(x) = N(x) - (Dx - 1)[N(x-) + N(x+)] \tag{4.3.8}$$

Equations (4.3.6) and (4.3.7) follow immediately from (4.3.1) and (4.3.2) regardless of the value of  $Dx$ . Equation (4.3.8), though not valid for all values of  $Dx$ , is valid for the value of  $Dx$  specified by (4.3.5). This may be demonstrated by equating the right hand side of equations (4.3.3) and (4.3.8). Substituting the expression for  $Dx$  from (4.3.5), and simplifying, the result is an identity.

Equations (4.3.6) to (4.3.8) are not the final equations however. When all the multiples of five are considered together, rather than in isolation, the increments to the number of persons intermediate between two successive multiples of five are made

independently from the lower and upper multiples of five. That is; ages  $x-4$  and  $x+4$  get a double dose of re-allocation. Thus (4.3.6) and (4.3.7) must be altered somewhat and (4.3.8) re-written in an equivalent but alternative form as:

$$N'(x) = N(x) - (Dx - 1)[N(x-5) + N(x+5)] \quad (4.3.9)$$

Equations (4.3.6) and (4.3.7) become one and the same equation, which can be written as:

$$\begin{aligned} N'(x) &= N(x) + (Dx - 1)[N(x-5) + [D(x+5) - 1]N(x+5)] \\ &= Dx + D(x+5) - 1 \end{aligned} \quad (4.3.10)$$

Equations (4.3.9) and (4.3.10) are Feeney's basic estimating equations.

They are valid for  $x = 0, 5, 10, \dots, c-5$ , where  $D_0$  and  $D_c$  are taken equal to one,  $c$  denoting the age (also a multiple of 5) that begins the open ended age group. The adjustment procedure specified by (4.3.9) and (4.3.10) is iterated until the value of  $D_x$  converges to as close to one as desired. It is found empirically that convergence always occurs. The number of persons at single years of age are found by interpolating linearly the final adjusted numbers of persons at ages that are multiples of five.

#### SIMILARITIES OF FEENEY'S METHOD TO A NINE-POINT MOVING AVERAGE

Let us consider the implications of Feeney's requirement that  $D_x$  converges to one. If  $D_x = 1$ , equation (4.3.5) implies that:

$$1/9[N(x-5) + N(x) + N(x+5)] = 1/8[N(x-4) + N(x+4)] \quad (4.3.11)$$

The quantity on the left hand side is a nine - point moving average. The quantity on the right hand side is an eight - point moving average that includes the same numbers except for  $N(x)$ .

For the two quantities to be equal, the final adjusted value of  $N(x)$  must be equal to a nine - point moving average of the final adjusted value of  $N(x-)$ ,  $N(x)$  and  $N(x+)$ . This suggests that a nine - point moving average procedure, or its repeated application, might yield approximately the same results as the Feeney's procedure.

#### 4.3.2 APPLICATION OF THE NINE - POINT MOVING AVERAGE PROCEDURE (THE SAXENA - GOGTE TECHNIQUE) TO KENYA'S DATA.

Step 1: The age distribution, derived by the nine - point moving average, is obtained by adding the observed four adjacent single year values on the extremes to the respective average of the nine terms centered at the middle. That is; the adjusted number at 0-4 is obtained by adding the recorded numbers at 0, 1, 2 and 3 to the nine - point moving average at age 4. (4 being the earliest age for which a nine - point moving average can be computed). The adjusted numbers at 65-69 for 1969, and 70-74 for 1979, is similarly obtained by adding the recorded numbers at ages 66, 67, 68 and 69 to the nine - point moving average at age 65. (The latest age for which a nine - point moving average can be computed is 65 for the 1969 census and 70 for the 1979 census). These adjusted values, denoted by  $5N'(x)$ , are entered into columns (2), (4) and (6) of table 4:6 for females, males and the combined sexes respectively.

Step 2: The adjusted populations for 5 - year age groups are put summary from as in table 4.7. The totals of these adjusted populations is generally lower than the enumerated totals. The ratio of the enumerated to the adjusted totals is worked out for the females and males, first; separately, then for the two sexes combined.

TABLE 4:7: ADJUSTED 5-YEAR AGE GROUPS - 1969 CENSUS

age, x	female	male	COMBINED
	5N'x (1)	5N'x (2)	5N'x (3)
0	1033461.	1044829.	2078289.

#### 4.4 THE DEMENY-SHORTER AND THE SAXENA-GOGTE METHODS COMBINED.

The Demeny - Shorter method is used to correct data that has already been adjusted by the Saxena - Gogte technique in order to correct for both heaping on multiples of five as well as systematic age misreporting. It would be useful to compare the results obtained by applying the Saxena - Gogte technique followed by the Demeny - Shorter method and that obtained when the Demeny - Shorter method is applied first, followed by the Saxena - Gogte technique. However, the second case is not possible since the Saxena - Gogte technique utilizes data on population by single years of age, whereas data adjusted by the Demeny - Shorter method is in five - year age groups. The 1969 and 1979 census age distributions that have been corrected by both the Demeny - Shorter and the Saxena - Gogte methods combined are given in tables 4:10 and 4:11 for the females and males, respectively.

4.5: CORRESPONDANCE BETWEEN THE TECHNIQUES OF DETECTING AND OF CORRECTING AGE ERRORS

It is important to study the correspondence between the techniques of detecting and those of correcting age errors so as to determine the method that is most appropriate and efficient in correcting age errors in Kenyan data. That is; based on the assumption that the techniques of detecting age errors are accurate enough in identifying the types of errors existing, it would be logical to expect that very little, if any amount of error will be detected in the sufficiently corrected data.

In this section, the correspondence between the age specific growth rate technique and the two techniques of correcting age distributions, namely; the Saxena - Gogte technique and the Demeny - Shorter method, is examined. In the first case, the two methods are considered separately and then the second case looks at the result of combining the two methods. This will help to identify the method that gives the most accurate estimate of Kenya's age distribution. It is not possible to study the correspondence between the age ratio technique and the techniques of correcting age misreporting because the application of the age ratio technique requires data on population by single years of age where as the corrected data by the techniques considered here are in five - year age groups. However, this is not a very serious limitation because the age ratio technique only identifies age heaping where as of more concern to a demographic analyst is age mireporting that carries people across age group boundaries. This type of error is sufficiently detected by the age specific growth rate technique.

4.5.1: CORRESPONDENCE BETWEEN THE AGE SPECIFIC GROWTH RATE TECHNIQUE AND THE SAXENA - GOGTE TECHNIQUE

The age specific growth rate technique is used to detect age misreporting in the data already adjusted by the Saxena - Gogte technique by entering the 1969 and 1979 female populations adjusted by the Saxena - Gogte technique into columns (1) and (2) of table 4:12 and then working out the mortality levels corresponding to the various age groups as explained earlier in section 3.1 of chapter 3. Figure 4:3 gives the graph of mortality levels against age for the females.

TABLE 4:12: CORRESPONDENCE BETWEEN THE ASGRT AND THE SGT - FEMALES

There appears to be very poor correspondence between the age specific growth rate technique and the Saxena - Gogte technique. In fact, with respect to the age specific growth rate technique, the Saxena-Gogte technique appears to worsen the data as far as age misreporting is concerned. The Saxena - Gogte technique therefore is not by itself appropriate in correcting errors identified by the age specific growth rate technique.

It should be noted that the age specific growth rate graph should be horizontal when there is no age misreporting.

CORRESPONDENCE BETWEEN THE ASGRT AND SGT  
Fig 4:3 FEMALES

Fig 4:4 MALES

4.5.2: CORRESPONDENCE BETWEEN THE AGE SPECIFIC GROWTH RATE TECHNIQUE AND THE DEMENY - SHORTER METHOD

The age specific growth rate technique is used to detect age misreporting in data already adjusted by the Demeny - Shorter method. The 1969 and 1979 female population data, adjusted by the Demeny - Shorter method are entered into columns (1) and (2) of table 4.16 and the mortality levels corresponding to various age groups worked out as explained earlier in section 3.1 of chapter 3.

Figures 4:5 and 4:6 give graphs of mortality levels against age for the Kenyan females and males, respectively.

There is a very close correspondence between the age specific growth rate technique and the Demeny - Shorter method. The age specific growth rate graph is almost horizontal but starts declining slightly at the older ages.

CORRESPONDENCE BETWEEN THE ASGRT AND DSM

4.5.3: CORRESPONDENCE BETWEEN THE AGE SPECIFIC GROWTH RATE TECHNIQUE AND THE DEMENY - SHORTER AND SAXENA - GOGTE METHODS COMBINED.

The age specific growth rate technique is used to detect age misreporting in data already adjusted by the Demeny - Shorter and the Saxena - Gogte methods combined. The 1969 and 1979 census population data, adjusted by both the Demeny - Shorter and the Saxena - gogte methods are entered into columns (1) and (2) of table 4.20 and the mortality levels corresponding to various age groups worked out as explained earlier in section 3.1 of chapter 3.

Figures 4:7 and 4:8 give graphs of mortality levels against age for the Kenyan females and males, respectively.

The correspondence between the age specific growth rate technique and the two methods combined appears to be better than the correspondence with either of the individual methods. The Saxena - Gogte technique corrects for heaping on multiples of five whereas the Dememny - Shorter method mainly corrects systematic age misreporting that carry people across age group boundaries. A combination of the two methods appears to give the most accurate estimate of Kenya's age distribution.

CORRESPONDENCE BETWEEN ASGRT AND DSM AND DSM + SGT

#### 4.6 THE EFFECT OF CHANGES IN ASSUMPTIONS REGARDING CENSUS COVERAGE, KENYA'S MODEL MORTALITY LEVEL AND LIFE EXPECTANCY AT OLD AGE.

It is important to study the extent to which some of the assumptions made in this chapter could have affected our final results. First, in the Demeny - Shorter method, it is assumed that the model mortality level of the population under study is known. In this application, the level used was that obtained by Mudaki (1986). However, the mortality levels obtained by various methods are not very consistent and it is therefore necessary to examine the extent to which a wrong choice of a model mortality level might have affected our findings. The other assumption made in the Demeny - Shorter method was that the total size of the population was enumerated correctly, or at least that the degree of coverage of the two censuses was reasonably close. Again, the estimates of the relative coverage of the two censuses as obtained in chapter II by Hill's technique and the Palloni - Kominski method are not consistent. It is therefore necessary to find out if better results would have been achieved if we had adjusted for census coverage. Finally, in the application of the age specific growth rate technique, it is required that we know the life expectancy at the age beginning the open age interval, that is;  $e(70)$  in this case. Several life tables have been constructed for Kenya and different methods appear to give different values of  $e(70)$ . In this study, the values of  $e(70)$  used are from the analysis by Mudaki (1986). There is however no reason to suppose that these particular values are the most accurate and thus it is necessary to find out if using an alternative value could have affected our

results.

#### 4.6.1 THE EFFECT OF CHANGES IN RELATIVE CENSUS COVERAGE

Before applying the Demeny - Shorter method, the enumerated 1979 population is adjusted for census coverage so that the enumeration completeness in the two censuses is similar. First, it will be assumed that the 1979 census coverage was 95% complete with respect to the 1969 census coverage. In the second case, it will be assumed that the 1979 census coverage was 105% complete with respect to the 1969 census coverage. This has been shown in tables given in appendix H. Figures 4:9 and 4:10 on the next page give corresponding graphs for the females and males respectively.

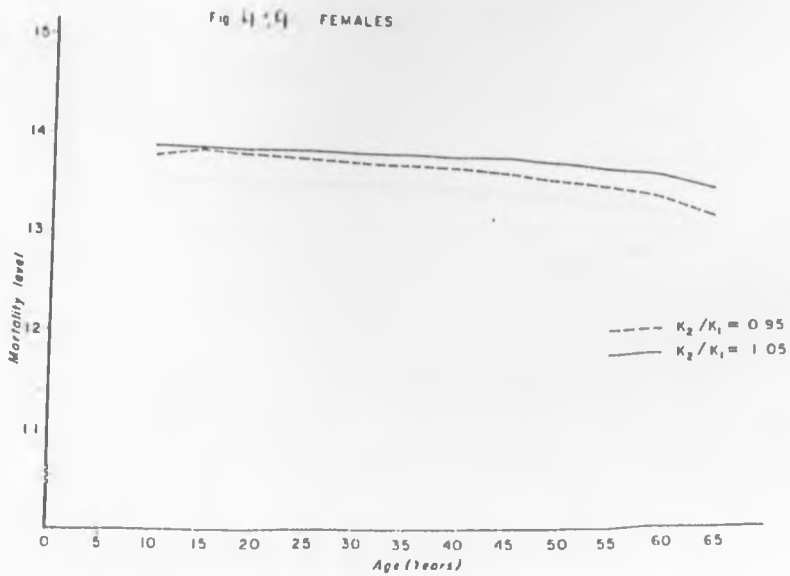

#### 4.6.2 THE EFFECT OF CHANGES IN MODEL MORTALITY LEVEL

In the application of the Demeny - Shorter method, it requires that we know the model mortality level of the population under study. First, it is assumed that the mortality level is 14, North model, then that the level is 15. This is done for both females and males as shown in tables given in appendix I, along with figures 4:11 and 4:12 given below for for the females and males, respectively.

#### 4.6.3 THE EFFECT OF CHANGES IN LIFE EXPECTANCY AT OLD AGE

In the application of the age specific growth rate technique, it is required that we know the value of  $e(A)$ , where  $A$  is the age beginning the open age interval. In our case  $A = 70$ . First, will assume that  $e(70) = 5$ , then that  $e(70) = 10$ . The values of  $e(70)$  that would give ideal cases (that is; horizontal graphs) are also considered.

EFFECT OF CHANGES IN CENSUS COVERAGE

EFFECT OF CHANGE IN MORTALITY LEVEL (Used in the DSM)

Fig. 4.11 FEMALES

Fig. 4.12 MALES

EFFECT OF CHANGES IN LIFE EXPECTANCY (Value of  $e(70)$ )

Fig. 4:13 FEMALES

Fig. 4:14 MALES

Illustrations of the effect of changes in life expectancy at old age are given in appendix J, along with figures 4:13 and 4:14 given above for the females and males, respectively.

From the graphs, it is unlikely that either adjusting for census coverage, or an alternative choice of a model mortality schedule could have affected our results. The difference in the shapes of graphs obtained after adjusting for census coverage, when it is assumed that  $k_2/k_1 = 0.95$  and when  $k_2/k_1 = 1.05$  is insignificant. Also, choosing different mortality levels only shifts the graph up and down, but the pattern remains the same. However, the choice of the value of  $e(70)$  used in the age specific growth rate technique, appears to have an influence on the shape of the graph. The graphs for  $e(70) = 10$  are more horizontal than those for  $e(70) = 5$ . In fact, an almost ideal case is obtained when  $e(70) = 12.5$  for females and when  $e(70) = 12.0$  males. What this implies is that if the actual values of  $e(70)$  are closer to these ideal cases than the values used in this study, as is most likely the case, then our estimates of Kenya's age distributions are fairly accurate with respect to the age specific growth rate technique. However, since our main aim in this section was to estimate the age distributions, the choice of the value of  $e(70)$  is not a very crucial limitation as it only comes in when detecting age misreporting. We can therefore be fairly confident that the estimates of the age distributions obtained in this study are reasonably accurate with respect to the assumptions considered above.

CHAPTER 5

CONCLUSION AND RECOMMENDATIONS

5.1: INTRODUCTION

The main objective of this study was to estimate Kenya's age distribution, census coverage and death registration completeness. Specifically, the study set out to:

- (i) Estimate the relative coverage of the 1979 census with respect to the 1969 census coverage.
- (ii) Estimate the intercensal death registration completeness in Kenya.
- (iii) Identify the nature and extent of age misreporting in Kenya.
- (iv) Make appropriate corrections for age misreporting and thus attempt to estimate Kenya's age distribution.

To achieve the first two objectives, namely; to estimate the relative coverage of the 1979 census and the intercensal death registration completeness, Hill's extension of the generalised growth balance equation and the Palloni - Kominski method have been used. Both methods have used the 1969 and 1979 census population data by five year age groups and by sex, as well as the 1969, 1974 and 1979 registered deaths by five year age groups and by sex. To realise the third objective, the age ratio technique has been used to detect age heaping on specific ages, where as the age specific growth rate technique has been used to

detect systematic age misreporting that carry people across age group boundaries. The age ratio technique has utilized the 1969 and 1979 census data on population by single - year age distributions and by sex. The age specific growth rate technique has used the 1969 and the 1979 census data on population by five - year age groups. Finally, to achieve the last objective, the Demeny - Shorter method and the Saxena - Gogte technique have been applied separately, then jointly to correct for age misreporting. Following the correction of age errors, the correspondance between one of the techniques of detecting age misreporting, namely; the age specific growth rate technique and the techniques of correcting age errors has been studied to identify the method that is most efficient in correcting age misreporting in Kenya. The extent to which some of the assumptions made in the study with regard to relative census coverage, Kenya's model mortality level and life expectancy at old age, would have affected the estimate of Kenya's age distribution has also been looked into.

The two methods employed in this study to estimate the relative coverage of the 1979 census and intercensal death registration completeness do not give consistent results. Where as Hill's technique gives the relative coverage of the 1979 census with respect to the 1969 census coverage to be 97.11 percent for females and 98.79 percent for males, results from the Palloni - Kominski method indicate that the 1979 census coverage was 100.57 percent and 103.58 percent for females and males respectively. The estimates of the intercensal death registration are not

consistent either. Results from Hill's technique show that the completeness of intercensal death registration, relative to the 1969 census coverage was 18.25 percent for females and 26.18 percent for males, while the Palloni - Kominski method gives much lower estimates of 14.50 percent and 19.39 percent for females and males respectively.

The pattern of age heaping in the two censuses was observed to be quite similar with a fairly large component of digit preference. The terminal digits 0, 5, 8 and 9 were the most preferred in that order. There was heaping in all the ages ending in digit 0 and 5 with an exception of age 15. This was observed to be the case for both males and females. In both censuses, the degree of age heaping for both sexes was observed to increase with age. However, the pattern of systematic age misreporting among the females was observed to be quite different from males'. Among the females, considerable overstatement of age was observed for teenagers and those aged 45 years and above, while women aged 10 to 34 years tended to understate their ages. For the males, there was a tendency to over-report ages throughout the age distribution and in particular, among those in their late twenties and those aged over 40 years.

An examination of the correspondance between the age specific growth rate technique and the techniques of correcting age errors, namely; the Demeny - Shorter method and the Saxena - Gogte technique, first applied separately then jointly indicate that a combination of the two methods is more efficient in correcting age errors in Kenyan data than either of the

individual methods. In fact, the Saxena - Gogte technique in itself appears to worsen the data with regard to systematic age misreporting. Finally, a study of the effects of the assumptions made in the study regarding Kenya's model mortality level, relative census coverage and life expectancy at old age showed that it is unlikely that our estimate of Kenya's age distribution would have been significantly affected by these assumptions.

5.2: CONCLUSIONS

There are clearly many biases in Kenya's demographic data arising from both content and coverage errors. Even though no conclusions can be made from this study on the exact estimates of relative census coverage and death registration completeness, what is clear is that the relative coverage of the two censuses with respect to each other was fairly close and within the range of 95% - 105%, and that the average death registration for the intercensal period less than 25%. It would have been useful to compare the estimates of relative census coverage and death registration completeness obtained in this study with those already obtained by other sources to establish consistent estimates. Unfortunately, no study has ever been done in Kenya to estimate the relative coverage of the censuses. Furthermore, comparison of estimates of death registration completeness with those obtained by Nyokangi (1984) is not possible because Nyokangi's data on death registration was incomplete and the study estimated death registration completeness for a particular year, 1979, and not the intercensal period.

With regard to age misreporting, the observed pattern of digit preference on terminal digits 0 and 5 appears to be consistent with what had already been observed in other developing countries, indicating ignorance of age, particularly among the elderly. Observed heaping on terminal digits 8 and 9 could have been a result of assigning ages ending in these digits to those reporting a year of birth with terminal digit 0, since the censuses were conducted in August 1969 and August 1979 respectively. However, the pattern of systematic age misreporting observed, and the fact that age 15 was being avoided despite the fact that there is a universal preference for terminal digit 5, could best be explained in terms of socio - cultural or biological factors influencing the importance the society attaches to various ages or age groups.

In general, both death registration data and age data appear to be better for males than females possibly due to better education and better written records. The same reasons could be used to explain why the degree of age heaping in the 1979 census was slightly lower than that observed in the 1969 census. From the above conclusions, the following recommendations can be made.

5.3

RECOMENDATIONS

5.3.1: POLICY MAKERS

(1) Improvements should be made on education in general, and the population need to be informed of the importance of knowledge on age through formal or non-formal education. Equal opportunities should be given to both sexes.(2) The vital registration system should be intensified. This will not only help improve the completeness of death registration, but also the registration of births will help facilitate knowledge on age through provision of written records.

(3) Sufficient funds should be made available for the census operations, particularly for better training of enumerators. A properly trained enumerator has knowledge on the importance of accurate age reporting and will use every available information to obtain as accurate ages as possible even from the ignorant respondents.

5.3.2 FURTHER RESEARCH

(1) Further work should be carried out on the estimation of relative coverage of censuses and death registration completeness in Kenya using other appropriate techniques to establish consistent estimates.

(2) The cultural, socio - economic, demographic and enviromental determinants of age misreporting should be researched into so as to identify factors that have significant influence on age misreporting and thus be in a better position to make recommendations for policy makers.

(3) Further work should be carried out to examine other aspects of the quality of demographic data in Kenya, particularly those relating to fertility measures.
